FOREWORD

The public hearings on The Nature of Radioactive Fallout and Its Effects on Man had their origin in studies initiated over a year ago—in July 1956—by the staff of the Joint Committee on the general subject of long term radiation hazards, both from the military and peacetime atomic energy program.

During the summer recess, following the conclusion of the 84th Congress, the staff assembled background materials on fallout, with primary emphasis on the research aspects. Following official announcement of the hearings in March of this year a detailed technical outline describing the proposed scope and subject matter of the hearings was prepared by the staff. This outline and related problems were discussed informally with scientific experts in the fallout field. The outline and comments of the expert group were most useful and helpful in providing the necessary ground work for the hearings.

On April 18, 1957, a Special Subcommittee on Radiation under the chairmanship of Representative Chet Holifield of California was established to conduct the hearings and to look into radiation problems in general. The subcommittee, with the assistance of the committee staff, then set about the task of selecting a representative group of expert witnesses from the major scientific areas involved, and extending invitations to them to testify. An effort was made, in this regard, to achieve a balanced presentation and to provide an opportunity for the expression of varied points of view.

The hearings, which were all open to the public, were held on May 27–29 and June 3–7, and covered the major aspects of the fallout problem from its inception in nuclear weapons explosions to its effects on man. In all, some 50 witnesses either appeared personally before the committee or submitted statements for the record.

The staff has prepared a summary analysis of the hearings which is aimed at pointing up the more significant information which emerged from the hearings. This analysis does not cover all points that were discussed in the hearings. An effort was made to describe the general areas of agreement which developed and to delineate those areas in which unresolved questions still exist.

On behalf of the Joint Committee we would like to extend our sincere thanks to all the expert witnesses, who gave generously of their time and effort to make the hearings a success. We are also appreciative of the excellent support we received from the staff and from the committee's consultant, Dr. Paul Tompkins, technical director of the Naval Radiological Laboratory at the University of California, whose advice was most helpful in connection with technical questions which arose during the course of the hearings.

CARL T. DURHAM,
Chairman, Joint Committee on Atomic Energy.
CHET HOLIFIELD,
Chairman, Special Subcommittee on Radiation.

CONTENTS

(Pt. 2 contains further statements by leading scientists, together with statements and papers submitted for the record.)
(A detailed subject index is now being prepared and will be published at a later date.)

[1] Each witness was asked to submit a short professional biography. Most, but not all, of the witnesses did, or, as in the case of some Government witnesses, their departments did. In a few cases the biographies came from American Men of Science.
In some cases the JCAE staff has abbreviated or deleted from the biography, for brevity, no matter what the original source. These biographies are for information only and should not be regarded as a formal statement.

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

MONDAY, MAY 27, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION OF THE
JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to call, at 10:05 a. m., in the caucus room, Senate Office Building, Hon. Chet Holifield, chairman of the subcommittee, presiding.

Present: Representatives Holifield, Durham (chairman of the Joint Committee), Price, Cole, Van Zandt; Senators Anderson, Jackson, Hickenlooper, and Bricker.

Present also: Professional staff members, James T. Ramey, executive director, George E. Brown Jr., Paul C. Tompkins, consultant, and Hal Hollister, staff technical adviser.

Representative HOLIFIELD. The committee will be in order.

This is the opening day of public hearings by the Special Subcommittee on Radiation of the Joint Committee on Atomic Energy on the nature of radioactive fallout and its effect on man. The primary purpose of the bearing is to bring together in one forum competent scientific opinion on the various major aspects of the fallout problem. An effort has been made to have a well-balanced presentation, with witnesses representing varied points of view within the scientific community.

It is the committee's intention through the presentation of expert scientific testimony, to trace the fallout cycle from the moment of the nuclear explosion, through the scattering of radioactive debris in the atmosphere, its descent to the ground, and finally its effect on human beings, livestock, and agriculture. Each of the various scientific areas and disciplines involved will be considered in sequence and an attempt will be made at the conclusion of the hearings to bring together, through general discussion, some of the major points developed at the hearings. In particular, the committee hopes to be able to delineate those areas where we have knowledge from those where we have little or no knowledge, with a view to determining the areas of research which need more intensive effort.

It is not the purpose of the committee, in this set of hearings, to draw any moral, political, or philosophical conclusions; nor to get into other associated fields, such as disarmament. Nor is it our purpose at this time to cover in detail the question of hazards in connection with nuclear powerplants, or the matter of workmen's compensation for employee radiation hazards. These subjects might more appropriately be taken up in a subsequent series of hearings.

For the purposes of these hearings we will be devoting our attention mainly to the radioactive fallout problem from nuclear explosions and to a possible projection of what the hazards are. We will have before us in the next 2 weeks a representative group of top ranking scientists in their chosen fields who have generously consented to appear before the committee to give us their expert opinion on a problem which has caused untold concern and confusion among the people of this country and among our friends in foreign lands.

The suggestion has been made by the chairman to our scientific witnesses that their presentation be made in laymen's language as much as possible rather than in complicated technical terms. The committee hopes this will be possible so that the printed record of the hearings may be understood by persons from all walks of life. This request should not be interpreted as precluding the submission of statements for the record which by their nature must include technical terminology and formulas. We also recognize and hope that the hearings will provide valuable source material for students and professional scientists throughout the world.

The committee and staff will avail themselves of the opportunity to question witnesses during their presentation or at the conclusion of their testimony, in order to clarify points at issue or to expand the record on a particular subject. At certain times later on in the hearings we may wish to try the technique of having certain expert witnesses comment on the presentation of a principal scientific witness, with opportunity, of course, for rebuttal by the latter.

It is my sincere hope, and I am sure the hope of all the members of the committee, that these hearings will result in a better understanding of this difficult and complex problem. Such understanding is essential, it seems to me, if we are to develop sound national policies.

At this point, I would like to place in the record, without objection, the outline of the subject matter for the hearings which was prepared by Mr. Hal Hollister who is our technical adviser on the staff of the Joint Committee. I might say that the list of witnesses is not closed; it is subject to addition later on if the committee deems it necessary. We were also advised in the development of the outline and in the selection of witnesses by a representative group of scientists familiar with this field.

(The subject matter referred to follows:)

CONGRESS OF THE UNITED STATES

JOINT COMMITTEE ON ATOMIC ENERGY

April 29, 1957

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN—OPEN HEARINGS MAY 27–JUNE 7, 1957

GUIDANCE TO THOSE PRESENTING TESTIMONY

Scope of hearings

The hearings will deal primarily, but not exclusively, with the scientific (physical, geological, biological, and medical) subject matter associated with radioactive fallout. Matters of program, money and policy as they relate to the scientific research aspect will be dealt with. The hearings will also deal for background purposes with scientific subject matter in topics related to weapon-caused fallout such as fallout from reactor accidents, and the biological effects of radioactivity caused by events other than fallout.

Approach of hearings

The hearings are to educate the committee and the public about fallout, how it originates, what happens to it, why it constitutes a hazard, what our sources and methods of getting information are, how adequate our knowledge is, and what the program in research for the near future should be. The hearings thus amount to a report on the progress of research. But because fallout is of intense concern to the committee and the public from a hazards point of view, and because of differences of opinion as to the facts and conclusions as to fallout hazards and their control, a special effort will be made, by means of the hearings, to assemble and disseminate information that is understandable and useful.

The record of the hearings should help competent persons to make the following sorts of judgments:

(1) What actual experimental, clinical, or operational data is a given result based on;

(2) How good is existing data on a given subject;

(3) How good is our understanding of the phenomena for which data is being collected; how good are hypotheses used to relate data to arrive at results;

(4) What are the results, as opposed to the conclusions, of work to date;

(5) What data should be collected urgently, because such data might never again be available assuming a continuation of tests;

(6) What further should be done by way of standardizing definitions, assumptions, etc.;

(7) What information can specifically be earmarked for use by civil defense and other agencies as working information?

Plan of presentation

The following order of presentation has been worked out:

I. An organized presentation by expert witnesses chosen from qualified persons in particular scientific fields:

A. Presentation of "background statements" by experts in the field of physics, meteorology, geology, biology, and medicine, to be followed by questioning confined to and appropriate for the statement but not broadening the subject matter.

B. Presentation of detailed statements on specific topics that should be examined carefully because they are particularly relevant, important or controversial.

C. Presentation of testimony designed to pull things together and point out the impact of the situation as it stands:

(1) What we know, what we can predict and how surely we can predict it; what we don't know.

(2) What action might serve to change the situation.

NOTE.—Oral presentation by expert witnesses should attempt to present scientific data in a form understandable to informed laymen. More detailed and technical data may be submitted for the record to supplement oral presentation.

II. An open presentation by those working in the field, or interested members of the public who requested an opportunity to testify before the committee.

MAIN TOPICS OF THE ORGANIZED PRESENTATION

The organized presentation will be broken down into the following main topics:

I. Introduction.

II. Background information—Radioactivity and Radiation.

III. Background Information—Controlled Fission and Fusion Reactions and Their Potential as a Source of Hazard.

IV. The Natural Occurrence of Radioactivity and Radiation.

V. The Production of Radiation and Radioactivity by Detonating Nuclear Weapons.

VI. Atmospheric Transport, Storage, and Removal of Particulate Radioactivity.

VII. Local Fallout: The Mechanisms by Which It Can Affect Man and the Measures He Can Take To Minimize Exposure.

VIII. Delayed Fallout: The Behavior in Geological and Physical Processes and the Mechanism by Which Delayed Fallout Enters into the Biological Processes and Reaches Man.

IX. A Detailed Discussion of the Occurrence of Strontium 90 and Cesium 137 in the Atmosphere, Biosphere, and Its Uptake and Behavior in Man.

X. The Effects of Radiation on Man; Somatic Effects—Pathology; Genetic Effects; Methods and Standard of Radiation Protection as Applied to Fallout Problems.

XI. The Impact of the Present State of Affairs: Summary, Interrelationships, and Implications on Policy.

XII. The Impact of the Present State of Affairs: What should the Research Program in the Physical, Geological, Biological, and Medical Sciences Be?

CONGRESS OF THE UNITED STATES

JOINT COMMITTEE ON ATOMIC ENERGY

April 27, 1957

OUTLINE FOR OPEN HEARINGS: THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

May 27–June 7, 1957

("Oral" denotes topic to be presented before JCAE orally, but may be read from prepared text.)

("Insert" denotes topic to be presented by a prepared statement be inserted in the record but not presented orally.)

("Bibliography" denotes topic that should be covered, in addition to the above, by some references to the literature.)

Any one or all of these methods of presentation may be indicated for the topics below.

I. Introduction (oral).[1]

A brief discussion for JCAE orientation, along the following lines:

A. The general nature of radioactivity and radiation.

B. Why radioactivity, radiation, and nuclear energy are closely associated.

C. Man's relationship to radioactivity and radiation.

D. The general nature of the biological effects of radioactivity and radiation.

E. The nature of the impact of applying nuclear energy for man's benefit on the health of individuals and on the health and welfare of the population as a whole.

F. Some factors that might be considered in deciding whether or not the hazards associated with radiation and radioactivity are worth risking to try to get the benefits expected from applying nuclear energy.

II. Background information—Radioactivity and radiation (oral, insert if desired, bibliography if desired).

A. The nature of radioactivity and radiation.

B. Mass, energy, and radiation.

C. Quantum and corpuscular radiation:

1. Energy relationships, the radiation field, definition of roentgen.
2. Fundamental particles.

D. Reactions of radiation with matter:

1. Ionization and energy transfer:
   a. Definitions, quantitative relationships.
   b. Specific ionization.
   c. Chemical and physical changes.
2. Penetration, absorption, attenuation, etc. of radiation:
   a. Definitions, quantitative relationships.
3. Induced radioactivity.
4. Secondary radiations.

E. The phenomenon of radioactive decay:

1. Modes of decay, decay chains, etc.
2. Definitions: half-life, average life, decay constant, curie, relation between mass, half-life, and curie for different isotopes.

F. Neutron radiation:

1. Special characteristics.

---

[1] To be preceded by opening statement by the hearing committee chairman to orient for the record the purpose, scope, and approach of the hearings.

G. Neutron fission and fission chain reactions:

1. Fission, number of neutrons released, energy spectrum, prompt and delayed neutrons, fraction of total.

2. Fission energy release, its nature and distribution by type (radiant, kinetic, potential, etc.), primary and secondary fission energy.

3. Fission products: Yield versus mass number, physical and chemical properties (particle size, vapor condensability, water solubility, etc.).

a. Radioactive decay of fission product mixtures, the simple models.

b. The limits of validity of the $t^{-1.2}$ law.

H. Nuclear fusion and thermonuclear processes:

1. Contrasts between fusion and fission, relationship to binding energy, energy and neutron release per unit weight of material consumed, etc.

2. Products and energy produced, including neutrons, gamma rays, and alpha particles.

3. Radioactivity of fusion products.

J. Particle accelerators and X-ray machines as sources of radiation and radioactivity:

1. The potential radiation hazards associated with accelerators.

III. Background information—Controlled fission and fusion reactions and their potential as a source of hazard (oral).

A fairly brief discussion for orientation, along the following lines:

A. Controlled fission reactions and nuclear reactors:

1. Types and characteristics of neutron chain reactions as employed in reactors.

2. Prompt and delayed neutrons and their role in control.

3. Other reactor characteristics that lend themselves to application for control.

4. Types and characteristics of reactors (from hazards standpoint):

a. Research, test, power, production.

b. Liquid fuel, solid fuel, homogeneous.

5. Sources of radiation and radioactivity hazards from reactor operation, associated chemical processing, and waste disposal, including liquid and gaseous effluents (bibliography, including recent AEC report).

B. Controlled thermonuclear reactions:

1. Contrast control problems with fission reactor situation.

2. Compare as potential source of radiation and radioactivity hazard.

a. Time schedule for controlled TN development.

b. Possible place in meeting power demand of future.

IV. The natural occurrence of radioactivity and radiation (oral, inserts, and bibliography).

A review and discussion of this topic, citing as appropriate such treatments as appear in the National Academy reports, the United Kingdom Medical Council report, the World Health Organization report (Sievert), the Government of India study, the statement by Dr. Warren Weaver (hearings, Foreign Relations Subcommittee, January 16, 1957), the British Journal of Radiology (29, pp. 409–417, 1956), and Dr. Libby's article in Science:

A. Naturally occurring radioactive materials and decay products and radiations.

B. Cosmic radiations, composition, characteristics, effect of altitude.

C. Spontaneous fission and induced radioactivity.

D. Measurement methods and limitations of the data.

V. The production of radiation and radioactivity by detonating nuclear weapons (oral, inserts, bibliography).

A. Description of nuclear weapon explosion:

1. Heat, blast, radiation, and neutron production in a bomb—rough models for scaling and attenuation.

2. Division of radiant energy into:

a. Prompt gamma and X-rays

b. Kinetic energy of neutrons—induce activity and cause direct damage

c. Potential energy which will manifest itself as—

(1) Direct fission product activity.

(2) Induced radioactivity (e. g. C^{14}).

B. The effect of weapon type and size from the point of view of fallout produced, both local and delayed.

C. The effect of the type of burst on the radiation and radioactivity resulting and on the fallout produced:

1. Air bursts.
2. Ground or surface bursts.
3. Underground bursts.
4. Underwater bursts.

VI. Atmospheric transport, storage, and removal of particulate radioactivity (oral, inserts, bibliography).

A. The types of fallout defined and described, and the conditions under which each type is produced—physical characteristics of particles, cloud formation, condensation, etc.

B. Local fallout:

1. The predictability of local fallout:
   a. Theory of predicting fallout.
   b. Models of radioactivity within the cloud (both Nevada and PPG), dependence on type and yield of weapon and type of scavenging material.
   c. Meteorological transport, examples of fallout under different winds, and in massive attacks.
   d. Uncertainties in model and meteorology.
   e. Weathering and redeposition of particles.
   f. Decay.
2. Observed patterns of local fallout:
   a. Patterns of external radiation in Nevada and the PPG.
   b. Radiation levels as a function of time. Radiation dose to unprotected persons as a function of time of fallout from fallout.
   c. Fractions of fallout observed locally.
   d. Factors affecting patterns of fallout.
   e. Physical, chemical, and radiochemical properties.
   f. Deposition of toxic materials.

C. Intermediate and delayed fallout:

1. The production and distribution of fallout in the atmosphere:
   a. Dependence on height of burst, yield, type of explosion, and scavenging material.
   b. Observed or inferred physical, chemical and radiochemical properties, with special reference to fractionation.
   c. Division of material: (local), tropospheric, and stratospheric; determining conditions.
2. Transport through and removal from the atmosphere:
   a. The stratosphere:
      (1) Transport, mixing, possible methods of removal.
      (2) Storage time; cumulative worldwide fallout as a function of time; predictions of future fallout from single event; from past weapons tests.
      (3) Sources of information; measurements and estimates of radioactivity in stratosphere.
   b. The troposphere:
      (1) Tropospheric removal processes; storage time:
         (*a*) Precipitation, interception, dry deposition.
      (2) Possible regions of unusual removal (fallout) because of meteorology or topography:
         (*a*) Exposure to prevailing winds and the sometimes accompanying effect, orographic rainfall.
         (*b*) Effect of large bodies of water on the distribution of fallout on adjoining land areas.
      (3) Meteorological tracking and other discussion of transport.
3. Observed deposition on the ground:
   a. Geographical distribution; dependence on physical factors
   b. Physical, chemical, and radiochemical properties, with special reference to fractionation.
   c. Measurement techniques and limitations of the data:
      (1) gummed paper, (2) gauze, (3) pots, collection of rainfall, and (4) soil samples.
4. Quantitative predictions of future fallout:
   a. From past tests.
   b. From future tests.

D. Interrelationships between study of fallout and study of meteorology; contributions of fallout studies to meteorology.

VII. Local fallout: The mechanisms by which it can affect man and the measures he can take to minimize exposure (oral, inserts, bibliography).

A. The relative importance of external radiation compared with internal radioactive emitters for the local fallout situation:

1. The source of the external radiation:
   a. Properties.
   b. Decay.
2. Internal emitters:
   a. Radioiodine, inhalation and ingestion.
   b. Other emitters.

B. Shelter and shielding and their effects.

C. Other immediate emergency measures that can reduce hazard.

D. Dose and dose-rate versus time.

VIII. Delayed fallout: The behavior in geological and physical processes and the mechanisms by which delayed fallout enters into the biological processes and reaches man (oral, inserts, bibliography).

A. The relative importance of internal emitters compared with external radiation in general for the long-run fallout situation (other than local fallout).

1. Factors of interest; criteria for deciding what radiation and which emitters should be worried about:
   a. Yield.
   b. Half-life.
   c. Physical distribution.
   d. Physical, chemical, and radiochemical properties.
   e. Uptake by plants from soil.
   f. Uptake by animals and man from diet, water, and air.
   g. Retention and distribution in man.

NOTE.—This topic up to this point is primarily an orientation for the detailed treatment to follow in the remainder of this and the following topics.

B. Deposition on and migration in soil and transport by surface waters.

1. Dependence on chemical properties:
   a. Strontium.
   b. Cesium.
   c. Plutonium.
   d. Rare earths.
2. The effect of river basin and ground water flow patterns; the effect of porous substructure such as Idaho lavas; the effect of inland sinks such as Salton Sea.
3. Effect of soil type and rock structure.
4. Mechanisms for fallout penetration into soil.
5. Decay.

C. The effect of agricultural practices on the distribution of fallout.

1. Possibilities for modifying agricultural practices.
2. Possibilities for liming soils.

D. The effect of fallout on water supplies for human, agricultural, and industrial use.

1. Possibilities for water treatment.

E. Possibilities for modifying present food collection and distribution and handling systems to guard against hazard.

F. Behavior in oceans mixing above thermocline, waste-disposal techniques, and ultimate effects.

G. Entry into biological processes, including man's food chain.

1. Deposition and retention on surfaces of vegetation.
2. Uptake by vegetation from soil.
   a. Characteristics for various plants and various radioactive materials:
      (1) Strontium.
      (2) Cesium.
      (3) Rare earths.
      (4) Plutonium.
   b. Dependence on soil characteristics.
   c. Other factors: decay, biological half-life, effective half-life.
3. Soil-plant discrimination factors.
4. Uptake by marine life and algae.
5. Uptake by animals, animal products, and man.

H. Retention and decay in animals and man.
1. Distribution of fallout in body tissues, fluids, milk:
a. Tendencies for localization:
(1) Radioiodine.
b. Dependence of equilibrium values on effective half-life.
2. Discrimination factors (preferential uptake of particular fallout products by particular species of plants, animals, and man); types and how measured or inferred:
a. Experiments for determining discrimination factors.
b. Numerical values for the various factors.
c. Combining values for the individual factors.

IX. A detailed discussion of the occurrence of strontium-90 and cesium-137 in the atmosphere, biosphere, and its uptake and behavior in man (oral, inserts, and bibliography). NOTE.—Sr-90 will be outlined in detail below.
A. Distribution, storage time, and fallout rate from atmosphere:
1. Combination of local and worldwide fallout of Sr-90 resulting from fractionation; long half-life; stratospheric holdup and mixing; decay.
B. Deposition on soil and plants—variations of Sr-90 level in environment as a result of weapons detonated in a relatively short period of time—from a few moments to 2 or 3 years.
1. Predicted fallout as a function of mixing and time.
2. Effects of retention of fallout on surfaces of vegetation.
C. The calcium model as a basis for predicting Sr-90 behavior.
1. Similarities and differences in behavior in the biosphere and in man.
a. How much do we know about calcium?
b. How much do we know about strontium?
2. Influence of amount of calcium in soil, diet; dilution and discrimination:
a. Dependence of occurrence of Sr-90 in animal and plant life on calcium in soil and diet.
b. Practicability of controlling occurrence of Sr-90 by adding calcium to soil and diet:
(1) calcium additives to milk.
c. Removal of Sr-90 from foods:
(1) calcium considerations.
D. Deposition in man—variations of Sr-90 level.
1. Function of age and time and location.
2. Observed occurrence in man and corresponding observed occurrences in soil and food.
E. Observed occurrence of Sr-90 in soil, food, and man (brief summary with detailed supplementary insert).
F. Predicted occurrence from weapons tests held prior to 1957:
1. Relation to accepted concentration standards (the basis of which is to be discussed later).

NOTE.—Cs-137 will be outlined below.
G. Distribution in the physical environment:
1. Half-life, stratospheric storage, chemical properties, similarities to potassium.
2. Deposition.
H. Occurrence in food supplies; probable sources:
1. Potassium model for discussing behavior of Cs-137 in biosphere.
J. Observed occurrence in humans—relationship to acceptable concentrations, on basis to be discussed later.
K. Predicted occurrence in humans as a result of weapons tests to 1957.

X. The effects of radiation on man (oral, inserts, bibliography).

SOMATIC EFFECTS—PATHOLOGY

A. Introduction and orientation: distinction between somatic and genetic effects, between acute effects of high-level radiation and long-term effects of low-level radiation and radioactivity, between damage per se and the standards developed to protect against damage.
B. Early effects of exposure of animals and man to external radiation:
1. Gamma and X-radiation: syndrome of radiation sickness:
a. Fallout on Marshallese: Rongelap, Uterik:
(1) Children recently returned to Marshall Islands.
b. Los Alamos incidents.
c. Other examples—radium.

2. Beta radiation—beta burns:
   a. Marshallese.
   b. Other examples—radium.

C. Early effects of exposure to internal radiation.

D. What are the criteria for picking out the harmful radioelements included in fallout?
1. How sure are we that all the harmful ones have been picked out:
   a. Strontium.
   b. Cesium.
   c. Rare earths.
   c. Plutonium.
   e. Iodine.

E. Delayed effects due either to single massive doses or to protracted chronic exposure; enumeration of effects of interest; dose dependence:
1. Examples.
2. Relationships between the two types of dosings.

F. Mechanisms and responses of man to radiation and radioactivity.
1. Briefly review chain of events:
   a. Physical effects.
   b. Biochemical and chemical effects.
   c. Cellular effects.
   d. Effects on whole organism.
2. Processes of physical interaction—physical effects:
   a. Significance of alpha, beta, gamma rays, and neutrons in the process.
   b. Significance of these rays with regard to penetration and whether introduced within the organism or arising from outside.
3. Chemical and biochemical changes:
   a. Direct effect of ionization on vital cell molecules.
   b. Indirect effects as a result of ionization of water in the presence of oxygen.
   c. Relationship and importance.
4. Cellular changes:
   a. Range of sensitivity of cells (list most sensitive—gonads—to least sensitive—nerve, muscle, bone).
   b. Relate sensitivity of nucleus to cytoplasm.
5. Effects on the whole organism:
   a. Range of survival dose on mammals (guinea pigs 200 r., rabbits 800 r.).
   b. Compare with nonmammalian radiation (virus, for instance, 1,000,000 r.).
      (1) Point out species variation and position of man.
6. Clinical syndrome in man (nausea and vomiting, hematopoietic depression, epilation, bleeding, etc.):
   a. Special place of hematopoietic response to radiation.
   b. Delayed effects.
      (1) Reduced longevity.
         (*a*) reduction in life expectancy—validity of concept at low levels of radition.
      (2) Production of leukemia and neoplasms (tumors).

G. Relationships of damage mechanisms to dosages.
1. Aplastic anemia, leukemia, and cancer as a result of exposure to radiation:
   a. Doses at which observable damage occurs; relationship of probability of damage to dose and dose rate; latent periods; doubling doses; relationship to tissue irradiated.
   b. Relative importance of cancer and leukemia under various conditions: external source; exposure of various critical organs to radiation from external and internal sources: lungs, gut, thyroid, skeleton, etc.

GENETIC EFFECTS

H. The nature of genetic effects: evidence, experience, data.

J. Relationship between radiation and change in mutation rate:
1. Natural mutation rate (2 percent).
2. Dose necessary to double mutation rate (50 r.).
3. Apparent linear nonthreshold relationship between dose and effects.
4. Cumulative character of genetic effects.
5. Mechanics of introducing and eliminating mutants in genetic pool

K. Predicted increase in mutation rate as a result of postulated increase in radiation levels from fallout:

1. Effects on population, as individuals and as a whole.

METHODS AND STANDARDS OF RADIATION PROTECTION AS APPLIED TO FALLOUT PROBLEMS

L. Standards for external-radiation effects: the concepts and definitions relating the amount of damage to the amount and kind of radiation causing the damage:

1. Definitions and concepts behind the units used for dose rate, cumulative dosage, biological effectiveness, etc.: the r, rad, rem, RBE; ionizing density; linear energy transfer.
2. Kinds of radiation and varying conditions of exposure.
3. Simplifying assumptions to get practical standards.
4. Calculation of dose and dose rate resulting from several kinds of radiation acting together.
5. Calculation of dose and dose rate resulting from one or several kinds of radiation acting on different parts of the body.

M. Standards for internal-radiation effects:

1. Definitions and concepts behind the measurement of internal body-burdens and dosages; the models used:
   a. Maximum permissible concentration.
   b. Safety factors:
      (1) Population versus occupational dose.
      (2) Young versus adult.
      (3) Whole body versus localized dose.
   c. Relationships between internal and external radiation dose.
2. Calculation of cumulative dose rates and dosages from external radiation and internal radiation of various kinds and under various conditions of exposure.

N. Philosophy: the assumptions and models behind the establishment of the standards:

1. Historical trends to the present and trends for the future.
2. The validity of the assumptions now used in the light of up-to-date knowledge.
3. Possibility of hazards resulting from low-level exposure: threshold considerations:
   a. Why do we not know whether or not there is a threshold for each of the various radiation effects of interest? How and when can we improve knowledge on this point?
   b. A radiologist may believe that the existence of a threshold is probable or he may not—what are the pros and cons?
   c. What about the acceptability of the currently recommended standards under either belief of (b)?
4. The probable trend of the standards for the future:
   a. Will new standards have to be developed to cover certain hazards not now adequately protected against?
   b. Are the standards defined in such a way that they can be ranked for any given situation so that the proper standard among several can be chosen to give the least likelihood of hazardous exposure? Is there any ambiguity if several standards apply?
   c. Do there now exist, or are there likely to be, different standards in use by the United States and other governments, or by the United States and States and municipalities?

SPECIFIC QUESTIONS FOR DISCUSSION

A. All low level effects are extrapolations from high level effects. How secure is this extrapolation? Discuss its relationship to the nonthreshold character of genetic effects, and to the question of threshold of bone cancer.

B. Are there any distinctions between temporary and permanent (long term) damages, between repairable and irreparable damage?

C. Are there special criteria for small groups of persons as compared with large populations with regard to radiation? Is there a difference between small and large populations? Between large populations and the whole population? Does the distinction apply only to genetic effects?

D. Discuss the known effects of radiation on such aspects of the human being as mental posture, personality, intelligence, other, etc.

E. Are there any chemical reinforcements of body defenses against radiation? What about drugs recently announced as being of possible use for X-ray dosages?

F. What is to be gained or lost by the recordkeeping recently proposed for each person covering his lifetime history of radiation dosage?

G. How much radiation and radioactivity was man naturally exposed to and medically exposed to before weapon firing began?

H. Are the dosage standards for individuals and populations adequate for Sr-90? What are the factors for genetics, skeleton age, age of individual, health of person, etc.?

J. How adequate is the radium model as a basis for predicting Sr-90 damage in man?

K. What is the behavior of radioiodine in man from a damage and dosage point of view? What about Cs-137, C-14, etc.?

L. Is the biological effect of Sr-90 and its daughter Y-90 similar or the same as that of external radiation of any sort?

XI. The Impact of the Present State of Affairs: Summary, Interrelationships, and Implications on Policy (oral, inserts, bibliography).

A. In essence, what is the state of our knowledge in the areas discussed as relevant to the "fallout problem"; what do we know about:

1. The amount of radiation and radioactivity released by weapons fired to date.
   (a) by the United States.
   (b) by others.
2. The amount of local and delayed fallout created by these weapons.
3. Where this fallout is:
   (a) How much has decayed.
   (b) How much has fallen out and where.
   (c) How much is still up there and where.
4. What has happened to the ground fallout that has fallen out:
   (a) How much got on or in soil and where.
   (b) How much got on plants.
   (c) How much got in the ocean.
   (d) How much got elsewhere.
   (e) How much of all this has decayed after it fell out.
   (f) How much has directly affected man as external radiation.
   (g) How much as internal radiation.
5. The mechanisms by which fallout gets distributed in the atmosphere and on the earth.
6. The mechanisms by which fallout gets into the biosphere and to man—or gets to man directly.
7. The mechanisms by which exposure to fallout leads to damage.
8. The amount of damage, if any, that man has so far sustained from fallout.
9. The mechanisms and measurement of biological damage from radiation.
10. The relationships between damage and dose.

B. Using the knowledge now available, how well can one predict—and how would one predict—the following:

1. The amount of fallout still to fall out from weapons already fired.
2. Where this fallout will fall out.
3. What will happen to it:
   (a) How much will decay or otherwise be harmless.
   (b) How much will directly affect man as internal or external radiation.
   (c) How much damage, if any, man will suffer from it.

C. Using the knowledge now available, how much information does one need to postulate concerning the characteristics of future weapon firings (test or war) so that one could predict with a certainty appropriate for policymaking purposes the same sort of information as discussed above for future firings?

1. Is such a prediction possible even assuming unlimited information concerning the firing characteristics? How would it be made?
2. Is a postulated rate of firing (yield per unit time) meaningful? What in principle does "present rate of firing" mean? Is a postulated rate of firing sufficient information by itself for making the sort of prediction named here?

3. How does one take into account such problems as divers sites of firing, firing of weapons whose characteristics are not known, differences in weapon type and burst?

4. Are the present criteria for biological damage adequate and are the related measurements adequate so that one could predict with a certainty appropriate to policymaking the future hazard, if any, owing to future weapon firings—even if he could forecast how much fallout there would be and what would happen to it? If the criteria are adequate, how are they put together?

5. If one had before himself a working definition of hazard that was satisfactory from a moral or ethical, social, political, and economic point of view, and if this definition was stated in terms of measurable or observable phenomena in nature (including man), does sufficient information exist so that he could determine, again with a degree of certainty appropriate to policymaking, whether or not a hazardous situation exists now or will exist in the future for various possible circumstances of weapon firings and radioactive fallout? Could he determine the degree of hazard? If their answers are "No," is it possible to state what information is lacking and how it might be obtained?

XII. The impact of the present state of affairs: What should the research program in the physical, geological, biological, and medical sciences be? (oral, inserts, bibliography).

A. Information sources and distribution.

1. Do and must private research groups depend on the Government, particularly the AEC, for most of their data? To what extent does the depth and breadth of the research program rest on what the Government is doing and on what the Government is willing to turn over to private research institutions?

2. Is scientific information adequately and promptly distributed and available?

3. To what extent are Government classification and other information-withholding mechanisms interfering with the distribution of information to the public and to scientific groups?

4. How much and what kind of data on radioactive fallout remain classified? What justification is given by AEC and other Government agencies for continued classification of such information? How much effort does the Government make to let it be known that material has been declassified after that action has actually occurred?

5. Is information exchange occurring properly between the United States and foreign countries and the U. N.? Is the United States adequately represented on international scientific and policymaking groups related to this problem?

B. The research program: What is the extent of research on radioactive fallout?

1. Is the AEC presented with a conflict of interest when it is required to act on the one hand as an agent in developing nuclear weapons, and on the other hand as an agent in providing safeguards against weapon hazards? If a conflict does exist, what would be effective ways of removing or at least minimizing it?

2. How much of the research is being done by the Government and how much by private research groups under Government sponsorships and with Government funds?

3. Are there serious soft spots in either the experimental or theoretical aspects of the sciences related to fallout; in particular are there any that limit a thorough understanding of the civilian and military implications of fallout?

4. How well is the research program in balance?

5. Is the general level of the research program adequate in view of the obvious policy implications of fallout in such areas as weapons testing, nuclear weapons bans, civil defense, the military posture?

6. Is the scope of inquiry on fallout problems broad enough so that it is not likely that the United States could be surprised by an enemy using the properties of fallout in a manner that we have no notion of how to cope with?

7. Is the atmospheric, biospheric, and medical sampling program adequate? Should more work be done, for example, on determining the normal incidence of bone cancer in areas of various background levels?

8. What, if any, data should be sought after urgently on grounds that it may never again become available assuming tests continue; that is, what virgin data and what check points should be found?

9. Should the United States prepare, through cooperative programs, to process fallout samples from all parts of the world?

10. Are Federal funds made available for fallout research adequately protected?

11. Is cooperation between Government and non-Government research adequate?

12. If the program is inadequate, should Congress increase appropriations for fallout research?

C. JCAE information.

1. Should the results of fallout research be made available to and reviewed by the JCAE as well as the AEC?

2. Would the creation of a special group of scientists be an effective way of reviewing information and resolving differences of opinion?

Before announcing our leadoff witness, I would like to announce that this afternoon we will have the subjects of The Production of Radiation and Radioactivity by Detonating Nuclear Weapons, and Atmospheric Transport, Storage and Removal of Particulate Activity, and as witnesses we will have Dr. Alvin C. Graves, Los Alamos Scientific Laboratories; Dr. Frank Shelton, Armed Forces Special Weapons Project; General Alfred B. Starbird, Division of Military Application of the Atomic Energy Commission; and Dr. W. W. Kellogg of the RAND Corp.

Leading off today will be Dr. Dunham, Director of the Division of Biology and Medicine of the Atomic Energy Commission. First, I would like to qualify Dr. Dunham for the record.

I see you received your M. D. at the Rush Medical College of the University of Chicago, that you taught there for many years, and that you have served in various capacities with the Atomic Energy Commission since its establishment in 1946. Most recently you have been Chief of the Medical Branch and then Deputy Director, of the Biology and Medical Division of the AEC.

We are glad to have you with us today, Dr. Dunham. As I understand it, you are going to give a brief general background of the problem. Would you please proceed.

STATEMENT OF DR. CHARLES L. DUNHAM, DIRECTOR, DIVISION OF BIOLOGY AND MEDICINE, ATOMIC ENERGY COMMISSION [1]

Dr. Dunham. Mr. Chairman, I appreciate very much the privilege of being called to testify before your subcommittee on the very important subject of the nature of radioactive fallout and its effect on man. In my own capacity as Director of the Division of Biology and Medicine of the Atomic Energy Commission, I feel that I can properly claim a certain perspective on this subject which may be helpful to you as you prepare to hear testimony from the outstanding technical experts invited to detail for you from their own researches and experience the many facets of this problem.

---

[1] Date and place of birth: December 28, 1906; Evanston, Ill. Education: Bachelor of arts, Yale University, 1929; doctor of medicine, Rush Medical College, University of Chicago, 1933. Work history: University of Chicago, assistant and instructor, 1936–43; U. S. Army Medical Corps, medical officer; chief, Preventive Medicine Section, 1943–46; University of Chicago, assistant professor of medicine; medical consultant, 1946–49; Atomic Energy Commission, Assistant Chief, Medical Branch, Division of Biology and Medicine, 1949–50; AEC, Chief, Medical Branch, Division of Biology and Medicine, 1950–54; AEC, Deputy Director, Division of Biology and Medicine, 1954–55; AEC, Director, Division of Biology and Medicine, 1955—. (Submitted by Atomic Energy Commission.)

The one property of fallout from nuclear weapons which is of interest in connection with these hearings is its radioactivity. Radioactivity, of course, is not new. While it has been recognized by man for only the last 60 years, it has always existed in some degree throughout the earth—in rocks and soils, in the water we drink and in the food we eat, and of course, in our own bodies.

Perhaps the radioactive material best known to the public before the advent of strontium 90 was radium, of which the most commonly used radioisotope is radium 226. Radium, concentrated from certain ores, has long been an article of commerce. Its interest to man has been almost entirely due to its radioactivity; that is, to the fact that its atoms spontaneously change into atoms of another chemical element and, in so doing, emit radiation from their nuclei. Radiation from radium and from its radioactive decay products is used to activate the luminous dials of our alarm clocks and our wristwatches; in sufficient quantity it may be used to treat cancer or to test the integrity of a welded steel joint.

We recall also that, although small quantities of radium have always been one of the constituents of the human skeleton, a few years after the First World War the public was shocked that many painters of luminous dials and other radium workers were dying as a result of radiation from radium in their skeletons—from skeletal contents of radium thousands of times as large as those which occur naturally. In the ensuing 30 years, the radium industry has achieved high standards of safety in the handling of radium, while radiobiologists have developed an imposing amount of information concerning the effects of radiation on man and on other forms of life. Yet the phenomenal increase in the importance to man of radiations from radioactive materials from other sources during the past 15 years have made drastic demands upon this knowledge. The result is that, while the best informed radiobiologists are keenly aware of the limits of our knowledge, many persons with various degrees of understanding of the relationships involved are apprehensive, and many others are confused.

I believe it is the purpose of this hearing to examine as critically as possible the biological implications of possible increases in the exposure of man to radiations from radioactive materials and from other sources. The most immediate interest, since for various reasons this has been given the greater publicity, is exposure to radiations from those particular radioactive materials which have resulted, or may be expected to result, from the detonation of nuclear weapons.

Before the hearings go into detailed technical discussions, I would like to spend a few minutes trying to give some feeling for the nature of radioactivity, of radiation, and of the biological effects of radiation. While there are several hundred different radioactive isotopes, or species of atoms, they account for only 3 or 4 kinds of radiation of interest in these discussions. These radiations are commonly called ionizing radiations, because the amount of energy contained in a single unit of the radiation as emitted by an individual atom, is sufficient to disrupt or ionize other atoms by separating electrons from them.

One type of radiation which will be of frequent interest in these discussions has many of the characteristics of visible light. It is commonly called X-radiation or gamma radiation, depending upon its origin. X-rays are well known for their ability to penetrate relatively

large thicknesses of materials. Variations in penetration depending upon the density of materials are the basis for the diagnostic use of X-rays in medical practice and for their use in radiograph. Two other types are more like particles, much smaller than atoms but moving with speeds measured in thousands of miles per second.

Most of us have difficulty in comprehending the significance of the very large and very small numbers required to describe atomic processes. One's reaction to the statement that the radioactive materials normally in the body cause millions of such missiles to plow through the body each day may be terrifying, or dry, matter-of-fact, depending upon his knowledge of chemical and physical processes. It is much less impressive to say that as a result of this number of missiles moving through the cells of the body an average of 1 out of every 100 billion molecules is affected per year. In general, the effects on living cells of ionizing radiations are chemical in nature. Most of the chemical reactions which are induced differ in no way from the normal chemical reactions which occur in day-to-day body processes. Those induced by natural radioactivity are very few in number when compared with what is going on all the time. On the other hand, they are completely random in nature and consequently do not serve a physiological or useful function. Consequently, a basic question to be considered in these hearings is how much increase in the frequency of these random occurrences is required to represent a significant hazard to human welfare?

This question quite properly raises another. Why should we have any increase in our exposure to radiation? Let us stop a moment and consider one of the basic facts of life, namely, to attain any specific objective almost invariably involves the surrender of something else. Reluctance to face this issue is commonly described as wanting to eat one's cake and have it too.

The development of nuclear energy and the production of radioactive materials are insepaable. With moderate effort, we can prevent release of a large fraction of these materials. With greater effort we can further reduce the release. However, if we continue to reduce the fraction we are willing to release, we eventually reach a cost of control which makes the operation prohibitive. At some point we must balance the undesirability of further increase in the quantity of radiation to which we are subject against the benefits to be anticipated from whatever application of nuclear energy we are considering. To say that we will tolerate no increase in exposure to radiation is equivalent to saying that we will make no use of nuclear energy.

This dilemma applies equally well to the use of radiation in medical practice. A physician uses X-rays to diagnose an injury or a disease because he believes that the benefits to the patient outweigh any detrimental effect of the X-rays. Although the X-ray doses required for diagnosis are generally small, a physician could not justify exposure of the patient without some reason. A physician may use much larger doses on a patient suffering from cancer—in fact he may use doses which in themselves may induce cancer. The treatment is obviously justified when one weighs the anticipated benefits against the possible undesirable effects. In this case, the question is quite complex because, while some of the undesirable effects may be certain, the cure of the disease may itself be in doubt.

The production of greater or lesser amounts of radioactive materials is an inevitable result of nuclear explosions. In succeeding testimony, witnesses will describe the processes by which such materials are disseminated in the atmosphere and are eventually deposited on the surface of the earth where they contribute to the exposure of man to radiation, both from locations outside the body and as a result of ingestion of radioactive materials which have gained access to the food supply. You will be given factual data on present levels of fallout radioactivity on the ground and in our bodies. Other witnesses will discuss in detail the present status of our knowledge of the biographical effects of large and small doses of radiation, however incurred, and the bases for some of the differing views of the effects of very small doses of radiation.

I believe that one of the objectives of your committee in holding these hearings is to develop some basis for judging how undesirable any particular quantity of fallout might be. There is no question, of course, that any quantity of radioactive fallout is undesirable, just as any quantity of exhaust gases is undesirable. Likewise, there is no question that as we proceed downward from lethal amounts of fallout, such as might be widely experienced in a nuclear war, to no fallout at all, we pass through degrees of undesirability which decrease progressively to zero. In these discussions, we are seeking standards of evaluation which can aid us in weighing the degree of undesirability of any given level of fallout against the advantages which may be anticipated from activities which are inevitably accomplished by fallout.

Although the testimony which you have scheduled for these hearings does not include the major considerations which must be weighed against the undesirable nature of fallout in order to justify any particular amount, I am sure that neither the members of your committee nor individual witnesses can avoid thinking of fallout in such terms. It is my hope, and I am sure it is yours, that during the technical presentations of the biological effects of radiation, the discussions of opposing theories concerning these effects will not become confused by the controversial aspects of other policy considerations.

Thank you.

Representative HOLIFIELD. Thank you, Dr. Dunham, for your statement.

Dr. DUNHAM. Mr. Chairman, may I introduce into the record certain documents and papers which Dr. Libby has asked me to bring to the committee?

Senator ANDERSON. Can he indicate what they are, Mr. Chairman?

(The list of material referred to follows:)

1. Strontium 90 concentration data for biological materials, soils, waters, and air filters. Project Sunshine bulletin No. 12. By E. A. Martell. August 1, 1956. [AECU-3297 (Rev.).] (See p. 617.)
2. The Chicago sunshine method. Absolute assay of strontium 90 in biological materials, soils, water, and air filters. By E. A. Martell. May 1956. (AECU-3262.)
3. Radioactive strontium fallout. By W. F. Libby. Proceedings of the National Academy of Sciences, vol. 42, June 1956: 365–390. (See p. 1468.)
4. Current research findings on radioactive fallout. By W. F. Libby. Proceedings of the National Academy of Sciences, vol. 42, December 1956: 945–962. (See p. 1494.)
5. Radioactive fallout. By W. F Libby. Remarks before the spring meeting of the American Physical Society, Washington, D. C. April 26, 1957. (Proceedings of the National Academy of Sciences, in press.) (See p. 1519.)

6. Dosages from natural radioactivity and cosmic rays. By W. F. Libby. Science, vol. 122, July 8, 1955: 57–58. (See p. 1459.)
7. Radioactive fallout in the United States. By Merrill Eisenbud and J. H. Harley. Science, vol. 121, May 13, 1955: 677–680.
8. Radioactive fallout through September 1955. By Merrill Eisenbud and J. H. Harley. Science, vol. 124, August 10, 1956: 251–255.
9. Strontium 90 in man. By J. L. Kulp, W. R. Eckelmann, and A. R. Schulert. Science, vol. 125, February 8, 1957: 219–225. (See p. 694.)
10. Worldwide travel of atomic debris. By L. Machta, R. J. List, and L. F. Hubert. Science, vol. 124, September 14, 1956: 474–477. (See p. 162.)
11. Project Sunshine. Worldwide effects of atomic weapons. The RAND Corp. August 6, 1953. [R–251–AEC (Amended).]

Representative Holifield. This material will be received for consideration by the committee, and its staff, with the disposition to be determined by the committee.

Dr. Dunham. Thank you very much.

Representative Holifield. Are there any questions of Dr. Dunham at this time from members of the committee?

Representative Cole. Yes, Mr. Chairman.

Representative Holifield. Mr. Cole.

Representative Cole. Dr. Dunham, you indicated that man first discovered the existence of radioactivity 60 years ago. Would you mind indicating very briefly what the circumstances were in connection with that discovery?

Dr. Dunham. There were two circumstances. One, of course, was Bequerel's discovery of radioactivity in uranium ores, in which he was studying fluorescence and laid a piece of uranium ore against a photographic film. He left it in his drawer for several years, and found the film was faulty.

The other was the discovery of roentgen rays by Roentgen, who was at that time doing research with cathode rays.

Representative Cole. When was radium first discovered, or realized?

Dr. Dunham. About 1896. I do not recall the exact date. But the radioactivity of uranium was discovered about that time, and within a year or two Madame Curie was working industriously on separating out radium as the active principal.

Representative Cole. Radium was discovered along about the same time as the fact of radioactivity?

Dr. Dunham. That is right.

Representative Cole. In different elements was discovered?

Dr. Dunham. That is right.

Representative Holifield. Are there any further questions?

Representative Price. I would like to ask one question.

Representative Holifield. Mr. Price.

Representative Price. Dr. Dunham, in your statement you referred to the use of radium in painting luminous dials of watches. You made a general statement that there was found to be a number of the painters of these luminous dials dying from their work. Do you have any record of the number of such casualties?

Dr. Dunham. It was up toward a hundred. It occurred in the early twenties.

Representative Price. For what period of years were they engaged in the work before these casualties began to occur?

Dr. DUNHAM. Most of this work was done during World War I, painting dials not so much for watches, but for other military equipment. It was along about 1923 or 1924, I believe, that the first cases came to the attention of Dr. Martland.

Representative PRICE. Is there any way to give any appraisal of the amount of radiation which they were dealing with in that type of work, compared to the amounts of radiation which people in the atomic energy program are dealing with every day?

Dr. DUNHAM. Well, the quantities in total of radium were infinitesimally small compared to the amounts of number of curies we deal with today. On the other hand, the amounts they ingested were hundreds, and probably thousands, of times what are considered a maximum permissible body burden today.

Representative PRICE. Can you give any estimate on the relative comparison of the record of casualties as between the two different programs?

Dr. DUNHAM. We do not believe that there is anybody associated with the Atomic Energy Commission program, or the Manhattan District program who will have any such outcome as a result of ingestion of radioactive material. There are a few persons in the early days who got a little more plutonium, who were just above the permissible body burden.

Representative PRICE. What is the reason for the greater evidence of safety in the handling of greater quantities of radiation now than in the early days in the painting of luminous dials, used in very small quantities?

Dr. DUNHAM. I think it was the experience in the luminous dial industry that made everybody particularly careful.

As some of you will recall, the problem of internal emitters, specifically with reference to plutonium, was the most troublesome one, and the one which more effort was put into to control by very elaborate ventilating procedures, use of dry boxes, and the like.

Representative PRICE. That is all I have, Mr. Chairman.

Representative HOLIFIELD. Senator Anderson?

Senator ANDERSON. Dr. Dunham, I have seen an advance copy of a magazine article that is soon to appear in a very reputable magazine, and I do not want to spoil it for the magazine by going into details. But, among other things, it suggests that when these rounds of reactors are finished, that they will regularly discharge in the atmosphere considerably more radioactive fission products than many of the hydrogen-type bombs. Will there be a place in this hearing where that can be considered? Is it something that should be evaluated and explored?

Dr. DUNHAM. I do not know what the wishes of the committee are on that. It was our understanding that the hazards from reactors would be touched upon somewhat by Dr. Mills, who, I believe, follows me. But I do not think there is any place, as far as I know. Mr. Hollister would know the answer there.

Representative HOLIFIELD. The Chair might say that we do not intend to explore the hazards from nuclear reactors in detail in this particular set of hearings. However, we are certainly not precluded from going into it at a later time.

Dr. DUNHAM. Yes.

Representative HOLIFIELD. But we will, of necessity, have to refer to this type of radiation from time to time.

Dr. DUNHAM. Yes.

Senator ANDERSON. Do you think it would be possible to get a scientific appraisal of the total amount of radioactive fission products to be put into the atmosphere when Commonwealth Edison gets its reactor running, and when Consolidated Edison gets its reactor running, and when Detroit Edison gets its reactor running, and when we have a dozen other operations of this 100,000-kilowatt size?

Dr. DUNHAM. I think once the actual final design has been settled on, the characteristics known, it will be relatively simple to calculate that.

Senator ANDERSON. The design for Detroit-Edison must be pretty well decided, since they have broken ground for it. They are going to break ground for the Commonwealth Edison plant about June 14 or June 19. And Consolidated Edison is going to build. Could not somebody evaluate that?

Dr. DUNHAM. I think it could be done.

Senator ANDERSON. Has your office made any evaluation?

Dr. DUNHAM. We would work with the reactor radiation hazards group on it. We would be very happy to evaluate some information here. You are talking about the normal operation of reactors?

Senator ANDERSON. Yes. There has been a good deal said about the testing of atomic weapons, and I have some worries, along with others, about that. If we can ignore testing because the daily run-of-the-mill operations of these reactors is going to place more radioactivity in the atmosphere than testing, he should pay some attention to that, too, should we not?

Dr. DUNHAM. I think one should. I would be very surprising if this were the case, however.

Senator ANDERSON. How would we go about getting a jury that would give some sort of answer that the common people can trust? You can get one group of scientists together, and they say one thing, and you get another group together, and they say another thing. What does a man who is not a scientist have that he can tie to?

Dr. DUNHAM. I think it is always important to ask your questions of the scientist who has worked diligently on the particular subject at hand.

Senator ANDERSON. I do not know who Dr. Pauling is out in California, but he has some ideas, and Mr. Muller has some ideas, and various people have ideas. Are they to be excluded just because they do not work for the Atomic Energy Commission, or have any contract from them?

Dr. DUNHAM. No; this was not my intention. I was merely suggesting, in the particular reference to the reactor problem that you ask the question of reactor engineers who can define the amounts of releases that will normally take place.

Senator ANDERSON. They do not have too much experience themselves in the operation of a reactor to show what might take place.

Dr DUNHAM. I think the Commission has had a considerable experience with a variety of experimental reactors—small, but still they have the same inherent characteristics of the larger ones.

Senator ANDERSON. Yes; they had experience with the prototype that went into the *Seawolf*, but when it got there it performed differently than all the prototypes had performed. Therefore, should we only trust this theoretical appraisal?

Dr. DUNHAM. The only other answer is that this will have to be proven as these reactors are started up. But I think some very useful information could be developed prior to that.

Senator ANDERSON. We had a meltdown of the EBR, and we have had some other things going on. I realize it is nice to say you must get your answer from the person who is in the field, but probably along the line somewhere they had to take some new ideas back as far as Einstein's whole theory.

Dr. DUNHAM. Surely.

Senator ANDERSON. There are a great many scientists that are worried, are there not, Doctor?

Dr. DUNHAM. I think there is no question about it.

Senator ANDERSON. Did you read the news story, I believe, this morning, that somebody was circulating a roundrobin among scientists who might express their views?

Dr. DUNHAM. I am aware of that.

Senator ANDERSON. How do you account for the fact that these people can read all this nice literature that the AEC has put out, giving them absolute assurance, and still be scientists, and they are still worried?

Dr. DUNHAM. I wonder if they are so worried about the fallout as they are about the spread of nuclear war?

Senator ANDERSON. You mean they are not sincere?

Dr. DUNHAM. No.

Senator ANDERSON. What do you mean?

Dr. DUNHAM. I would like to call your attention to what Dr. Arthur Holly Compton said the other day.

Senator ANDERSON. I saw that. Everytime one man comes out on one side, the AEC produces one on the other side, and we who stand in between are preplexed.

Representative COLE. The record will not show what Dr. Compton said, and I suggest you allow him to indicate that.

Senator ANDERSON. Go right ahead, Doctor. What did Dr. Compton say?

Dr. DUNHAM. I am afraid I no longer have it with me. I brought it over this morning.

Senator ANDERSON. I am sorry. It will probably be better, if Mr. Cole is willing, to have it come at a later time.

Representative COLE. I was going to ask, could not Dr. Dunham give his understanding of Dr. Compton's statement, not quoting him verbatim, but the substance of his statement. I do not know what it was, and I seek to know what it was.

Dr. DUNHAM. His statement was generally to the effect that he was as sincerely interested in peace as Dr. Schweitzer was; that is why he was in Stockholm with the World Federalist Movement, which is a peace movement. But he felt that Dr. Schweitzer has grossly exaggerated the hazards of fallout; and further, this was not the way to approach a permanent peace in the world, by simply exaggerating the hazards of fallout from what was tested.

Senator ANDERSON. We have many witnesses, and I do not wish to prolong this. I would just hope, Dr. Dunham, because we all have a great deal of confidence in you—and justifiably so—that you might

indicate how we might go about reaching a determination as to how the average man can have his fears allayed. He looks to two conflicting groups of scientists, and they tell diametrically opposite stories. It is pretty hard for one in between to decide which one is right, and which one is wrong.

That is all.

Representative HOLIFIELD. Are there further questions?

Senator Bricker.

Senator BRICKER. Just one question. You said, I believe, a moment ago, in your colloquy with Senator Anderson, that in your judgment there is no anticipated danger of fallout from the reactor program?

Dr. DUNHAM. That is right.

Senator BRICKER. How far could it go before there becomes a danger of fallout?

Dr. DUNHAM. I think one can have a great many reactors operating normally without any serious pollution of the world.

Senator BRICKER. There is a degree of pollution that come from normal operation, is there not?

Dr. DUNHAM. Yes, but relatively small.

Senator BRICKER. Relatively small. Excessive pollution would only come from a breakdown?

Dr. DUNHAM. From a specific accident in a reactor.

Representative HOLIFIELD. Mr. Durham.

Chairman DURHAM. Since the Government Agency of AEC under your direction is, of course, one of the prime agencies from which we can secure information that is worthwhile, would you give to the committee just how many you have in your dpeartment, the number, and how you evaluate the problem, and give the committee a little background?

Dr. DUNHAM. Yes.

In the Division of Biology and Medicine, we currently have 67 people, including secretaries, mail clerks, and the like.

As you know the Commission's operations are generally by contract. We also have related to us in the New York office, the Health and Safety Laboratory, which has about 70 or 80 people who actually do technical scientific work on the analyses of fallout material and the like.

This relatively small staff means that we have to work very closely with our prime contractors, with people in other agencies, and at our university projects in leaning very heavily on them for guidance in the actual development of information.

Chairman DURHAM. Can you give the committee the number of contracts you have with medical institutions throughout the country, actively working on this subject?

Dr. DUNHAM. I do not know that I can limit it to medical institutions.

Chairman DURHAM. Not necessarily that, but I mean people that are in the field of biology and medicine.

Dr. DUNHAM. The whole field?

Chairman DURHAM. The whole field.

Dr. DUNHAM. This would be a matter somewhere between 500 and 550 at the present time, from little contracts of a few thousand dollars a year, to very large ones.

Chairman DURHAM. Then you have under your direction over 500 scientists, we would call them, in the field of biology, as to the radiation hazards on man?

Dr. DUNHAM. No. In the first place, they are not under our direction in that sense. In the second, many of these people are working in the peaceful uses of atomic energy in the field of agriculture and the like. On the other hand, there is a great deal of work that goes on, say, in the treatment of cancer which is terribly important to our understanding of the effects of radiation.

Chairman DURHAM. But, as I recall, in the Commonwealth Edison matter, in regard to the reactor safety, I believe you introduced in the hearings—I forget how many—almost a hundred pages, or something like that, of testimony as to the safety of that under your direction. Is that correct?

Dr. DUNHAM. That was not under my direction, but it was a Commission activity.

Chairman DURHAM. The work was primarily done by you, was it not, and your staff?

Dr. DUNHAM. I am not familiar with the document you refer to. We have about a hundred projects strictly in this field, related to fallout, if that is what you are speaking of. But I am not familiar with just what document was introduced.

Chairman DURHAM. When you people down at the AEC laboratories receive a complaint, or make a study, say, for instance, as you did on the radiation dial case, how do you proceed? Do you assign a group of biologists to that particular complaint?

Dr. DUNHAM. We find people who are interested in the problem, such as Dr. Evans of Massachusetts Institute of Technology, and give him all the funds he needs to go ahead and get ahold of these people, study them, and come up with answers.

Chairman DURHAM. There is no delay when you do have a complaint as to a hazard in entering into an investigation as far as your department is concerned?

Dr. DUNHAM. As far as a specific hazard goes, that is a little different. What I have been talking about is this long-term approach to the thing.

If we are aware of a problem somewhere, we usually advise the Health and Safety Laboratory, or an operations office that a hazard is supposed to exist, and send somebody out to look into it right away.

Chairman DURHAM. That is all, Mr. Chairman.

Representative COLE. Mr. Chairman, following up Mr. Durham's inquiry, which I think is very, very apt, could you indicate the number of scientists who are engaged in connection with these hundred contracts which you say the Commission has, with varied persons, from one person, I judge, up to an institution that may have several persons?

Dr. DUNHAM. That is right.

Representative COLE. But you say there are a hundred contracts the Commission has for study in connection with the field of radioactive hazards?

Dr. DUNHAM. Yes.

Representative COLE. How many scientists do you estimate would be involved in that overall study?

Representative HOLIFIELD. The Chair might state that the staff has asked for a complete breakdown of the contracts and the men assigned to these different contracts, and that will be furnished to the committee.

Dr. DUNHAM. I will be glad to submit it for the record (see p. 1393).

Representative HOLIFIELD. If you wish to respond in general, go ahead.

Dr. DUNHAM. It would be a number of times the number of contracts.

Representative COLE. As many as 500?

Dr. DUNHAM. Somewhere between 300 and 500, I would assume.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Dunham, in addition to the efforts that the AEC is making in this field, do you know of any other effort in the United States?

Dr. DUNHAM. Yes. The Public Health Service, through its Environmental Health Laboratory at Cincinnati, and its engineering laboratory, is making very important contributions. The Bureau of Standards is making very important contributions. The various branches of the Department of Defense are making important contributions, and the Department of Agriculture.

Representative VAN ZANDT. Do you coordinate your efforts with these various agencies that you named?

Dr. DUNHAM. Very definitely.

Representative VAN ZANDT. With respect to private industry—do you know of any corporation or business firm sponsoring a research program in this field?

Dr. DUNHAM. How broad an organization do you have in mind? You mean to look into the whole problem of radiation safety?

Representative VAN ZANDT. Yes.

Dr. DUNHAM. I do not know of any which has a whole division directed to that effort, other than in our prime contracts with large organizations. Some of those companies have a real effort in their home plants too, but probably not comparable in size or scope to, say, what we have at Hanford in radiological safety.

Representative VAN ZANDT. Is it proper for me to assume that the information at your disposal reveals the best cross-section of effort is being made in this country at this time?

Dr. DUNHAM. I believe that is right, because we have access to all the work being done in other Government agencies, in close liaison.

Representative VAN ZANDT. That is all, Mr. Chairman.

Representative HOLIFIELD. Senator Bricker.

Senator BRICKER. There are many university research programs being conducted at the present time in this field of radiation hazards; are there not?

Dr. DUNHAM. Very definitely, some with AEC funds, some with Health Service funds, some with university funds, their own endowment.

Representative HOLIFIELD. Thank you very much, Dr. Dunham, for your statement.

I might say the next witness, Dr. Mark Mills, of the University of California radiation laboratory, is a man of distinguished scientific background. He comes from one of the university projects, I understand, which is contracted for by the AEC.

Dr. Mark Mills, will you please come forward.

Representative COLE. Could I ask that you give us a brief synopsis of Dr. Mills' background?

Dr. MILLS. Mr. Holifield, I wonder if I could use the blackboard. I think it will be a little more understandable.

Representative HOLIFIELD. For your presentation?

Dr. MILLS. Yes, sir.

Representative HOLIFIELD. All right, Doctor, go ahead.

STATEMENT OF DR. MARK MILLS, ASSOCIATE DIRECTOR, UNIVERSITY OF CALIFORNIA RADIATION LABORATORY [2]

Dr. MILLS. First of all I would like to thank you for the opportunity to speak before you. I believe this is a very welcome review of a problem that is troubling people.

I would also like to say two things about my testimony:

First of all, I will mention something about biological effects in order to tie the physical quantities to biological quantities. It was my understanding this part of the testimony was to be background testimony, and it is very helpful in fixing ideas if one ties these things together.

On the other hand, I want to be quite explicit and disqualify myself as a biological expert. So this is just to help to jell ideas and not to represent any expert understanding of the biological effects of radiation.

Representative HOLIFIELD. Doctor, we had asked you to give us background information on radioactivity and radiation. We understand that.

Dr. MILLS. One of the things in the outline has to do with the roentgen, which is close to biological effects.

Finally, I wanted to say I am going to give a descriptive picture of matter as current physics thinks of it, without trying to explain where all of the notions come from.

Representative HOLIFIELD. The Chair will again request, as he will with many of the witnesses, probably, that you make your presentation in lay terms as much as possible, so that the members of the committee can understand it.

RADIATION AND RADIOACTIVITY

Dr. MILLS. Yes, sir. I hope very much it will turn out this way. I have been trying to do it in that way.

1. The nature of matter

In order to understand radiation and radioactivity and its effect, it is helpful to understand how physics people think of ordinary matter, or the matter we are used to, which comes in many different chemical kinds.

Ordinary matter is made up really of five ingredients.

---

[2] Date and place of birth: August 8, 1917; Estes Park, Colo. Education: Bachelor of science, California Institute of Technology, 1940; doctor of philosophy, 1948. Work history: Instructor, physics, California Institute of Technology, 1940–41; section chief, Jet Propulsion Laboratory, 1941–45; lecturer, jet propulsion, 1943–48; group leader atomic energy research department, North American Aviation, Inc., 1948–51; Director, Project SQUID, Princeton University, 1951–52; staff specialist, North American Aviation, Inc., 1952–53; group leader, theoretical physics, University of California Radiation Laboratory, 1953—. (Submitted by Witness.)

There are the three kinds of particles that you have probably heard of. One is the proton, which is the nucleus of the hydrogen atom. One is the electron, and one is the neutron.

These three kinds of particles are then joined together by forces to make up matter in various forms.

The forces that we know in nature are gravity, which is believed not to play any important role in ordinary matter—that is, it holds the stars together, but it does not hold the atoms together.

Electric forces, which we are used to. Originally there was lightning, I suppose, and later one has gotten a great deal of experience with electromagnetic forces in our large electrical industry.

These forces, then, are things man is used to, and are forces which man can see.

Finally, there are things called nuclear forces, of which we have only indirect knowledge, but we do know they surely exist.

Given then these three particles—the neutron, protron, and electron—and given the forces, nuclear and electric, we can then construct all the matter we know about.

I would like to sketch very briefly, then, some piece of matter.

First of all, there is the atomic nucleus, which contains neutrons and protons. It is customary in describing the atomic nucleus to give usually the number of protons, and the total number of particles, both neutrons and protons. The number of protons is given the symbol Z.

Representative HOLIFIELD. I suggest that you take the microphone in your hand, so that it will be easier for you to make your presentation.

Dr. MILLS. Yes, thank you.

The number of protons represented by the plus lines here, is called Z. Just count them up.

The number of neutrons represented by the little open circles is called N and the total number of particles in the nucleus is usually called mass number A. This is a sharp number. Its numerical value is very closely equal to the mass of the nucleus in the usual unit, but the actual mass and mass number are different things.

If you then take a nucleus and add to it electrons, as you are all used to, the symbol [indicating] with the electrons swimming around. This whole thing altogether is an atom.

In a neutral atom the number of electrons is equal to the number of protons, and the electrical charge, then, of the whole atom—since the protons are positively charged and the electrons are negatively charged, the total charge is zero, and the atom is neutral.

Now, I might mention a little bit how all these things look together. The neutrons have no electrical force associated with them, but they have a nuclear force. The protons have both a nuclear force and electrical force. The charge on them is what makes the electric force. So the neutrons and protons stick together by their nuclear force in this thing we call the nucleus, which is very small, 10 to minus 12 centimeters in size.

Then the electric force which the electrons and protons have for each other—the electrons feel no nuclear force—allows the electrons to be held attracted by the nucleus—the negative electrons are attracted by the positive charge of the nucleus and they hover around, making up the complete atom.

This, then, is a thing about 10 to minus 8 centimeters in size.

Now, if you stick several atoms together—here the little circles are supposed to be the electron shells, and the tiny circle in the middle is the nucleus. If I stick several atoms together, then I form a chemical substance or a molecule. Most of the matter we are used to is made up of molecules, groups of atoms. Essentially all of the chemical forces which hold molecules together, for example molecules of water, H_2O, and salt, NaCl, sodium chloride, have to do with juggling electrons. That is, the electrons tend to repel each other, but it turns out they can sort of see the two positively charged nuclei if brought near each other, and the net effect is that the atoms hold hands with electric force. So actually all of chemistry really has only to do with juggling electrons and the electrical forces.

2. The effects of radiation

Now I wanted to switch almost immediately to the problem of radiation and its effect.

One of the things one might do is describe one other situation, and that is the thing called an ion, and what is meant by ionization.

The simplest one, I think, is probably to look at a neutral atom. It, of course, happens with molecules, too.

Here is my nucleus. Here are a number of electrons all hovering around it. If I can disturb this some way—and I will return in a second to how—I can break off one of the electrons and essentially fracture the atom, but mainly in its electrical part, and have left then a fragment with a net positive charge. The remaining electrons will join up with other atoms.

This one [indicating] is transformed into these, and a number, 1 or 2 or 3 electrons. Each of these things that have a net charge is called an ion, and the process of making them is called ionization.

Now, radiation essentially can come from two places. First, of all, one can take any of these particles, the proton or the electron, and by various indirect ways, the neutron, and make them move very fast, and when they are moving fast, they are called radiation.

There is another kind of radiation which is called the gamma ray, and that is essentially a particle of light that Dr. Dunham spoke of, or radio wave. If it comes from an X-ray machine, that radiation is called X-rays. When a quantum of electromagnetic radiation comes from a nucleus, it is called a gamma ray. Instead of making radiation by machinery, it turns out that one can get radiation of this kind from the nuclei of unstable atoms.

Some of the atoms that are found on the earth naturally are already radioactive. Uranium, thorium, and radium are naturally radioactive atoms.

Essentially, somehow the atom is not happy the way it is, and ejects some of its nuclear particles, or possibly it makes and ejects an electron.

One can also by means of various machines, including things like a nuclear reactor or accelerator, make normal matter radioactive. This is called induced radioactivity.

I would just like to list the different kinds of radiation which I believe are pertinent for your review. There are some other kinds that are not very well understood, but I do not believe they are of practical concern here.

The normal radiations are alpha particles, beta particles, gamma radiation. I would like to add to this list, fission fragments, which I designated by "FF," and then the only other particle we really need, I believe, is the neutron.

Now, the alpha particle is essentially the nucleus of a helium atom. It contains 2 neutrons, 2 protons. Alpha particles emitted from actual radioactive materials like radium move at about one-twentieth the speed of light. Because of their strong electric field, when they go by, say, an atom or a molecule, this electric field can take hold of the electron on the atom, break it off, and now you have ionized this atom.

Representative HOLIFIELD. Dr. Mills, as you explain each one of these components, will you also give the half life, and explain what the term "half life" is, and also the power of penetration and the durability?

Dr. MILLS. Yes, sir. I beg your pardon. The half life I will come back to that—the half life is the property of the atom that is emitting the particle, rather than the particle itself.

I want to very quickly, if I could, list the particles and say something about them.

The alpha particles that occur naturally, and also occur mainly at the heavy elements of the atomic table—uranium, thorium, radium, protactinium, and so forth—generally have energies of 1 to 5 Mev. They have speeds of about one-twentieth of the speed of light. They go in air distances like 2 to 5 centimeters.

In tissue, which is of some interest for our current thinking, which I will say is approximately like water, these particles go essentially one one-thousandth of that distance, or .003 centimeter, say, or three-hundredths of a millimeter, and a very tiny distance.

Beta particles are also emitted from nuclei. They are very light. They are, of course, electrons of sometimes positrons. Beta particles are usually considered negative, just like this [indicating] that circles around the outer shell of the atom. Sometimes the nucleus can emit a positive beta particle, which is a special unstable particle which does not live very long in ordinary matter, and atoms are not made of positrons.

Essentially, these beta particles move with the speed of light—not quite, but very close to the speed of light when they are emitted.

For example, for 1 Mev. beta particle, can go distances like a few meters, say 3 meters, that is, 300 centimeters, about 10 feet, in the air, and in tissue they go a correspondingly shorter distance, about half a centimeter, say, in tissue.

Now it is convenient, in thinking about these, if you will forgive me, to bring in the fission fragment up here [indicating] and the gamma rays down there [indicating].

The fission fragments, which we will return to still again, are the fragments produced when a fissionable nucleus, such as uranium or plutonium, is fissioned by neutrons. The neutrons attack the nucleus, and the nucleus breaks in two.

The fission fragments weigh about a hundred mass units, and they carry energies like a hundred million electron volts, and, therefore, they move at about the speed an alpha particle moves, because their

mass and energy are up proportionately, and, therefore, their speed is about the same.

They will go about 2 centimeters in air, and, therefore, distances again like alpha particles, distances like three one-thousandths of a centimeter in tissue or water.

Now, all of these particles here—the alpha, beta, and fission fragments—have definite ranges. They are essentially a little projectile that goes plowing through matter until it runs out of gas, and then it stops and is not doing anything more.

The gamma ray, which is this little particle of light, does not have a definite range, and it interacts with matter in a hit-or-miss fashion (like a man running through a forest blindfolded—he will miss the trees for a while, and finally he smacks into one). Well, the gamma rays and neutrons both behave in this way in matter. They do not do much of anything until they more or less have a catastrophic collision.

Generally, the gamma ray interacts with electrons and turns its energy into fast beta rays. Fundamentally, this is what it does. So the effect of the gamma ray on matter is really the effect of beta rays on matter because it changes its energy into stirring up the electrons in matter until they make beta rays.

Chairman DURHAM. What causes that, Doctor?

Dr. MILLS. I think it is actually sort of visualizable this way, sir. I know these drawings are not very elegant, but you have this nucleus here [indicating], and here comes a gamma ray, and the standard picture one draws is a sort of a wiggly line. This gamma ray runs into the electron. Now, the reason the gamma ray and the electron interact is the electric charge on the electron. That is how the electron makes gamma rays itself, and how the gamma rays get hold of electrons.

The electric charge has to do—you see, the gamma ray is a piece of electromagnetic field, and when you move an electric charge around violently, you generate electromagnetic waves. It is sort of like paddling on the ocean and sending waves out. These are electromagnetic waves rather than ocean waves.

I beg your pardon. Was this helpful?

Chairman DURHAM. Yes, as far as I know.

Senator ANDERSON. We are certainly glad to have it in simple language.

Representative HOLIFIELD. Doctor, again I ask you, would you also give us the persistence of gamma rays as compared to beta rays?

Dr. MILLS. Yes, sir.

Representative HOLIFIELD. And their penetrability, their ability to penetrate matter, the ability to penetrate shielding?

Dr. MILLS. Yes, sir. I have not quite gotten it filled in.

Representative HOLIFIELD. All right.

Dr. MILLS. Gamma rays are able to go—let us talk about a 1-million-electron-volt gamma ray. In the air they go in the order of 10 to 100 meters, depending on their energy. In water they will go a distance of the order of 10 centimeters, and in lead they go distances of the order of 1 centimeter.

By that I mean this: They do not go a certain distance and then stop. They will go a certain distance and then there is a pretty good chance they will do something, and be stopped, or collected, or ab-

sorbed. But some of the special ones, with the poorer and poorer probability, can go greater distances than these characteristic distances I am talking about, tens of meters in the air, tens of centimeters in the water, and 1 centimeter in lead represents how far a strong beam of gamma ray goes before it is reduced to about half intensity.

Representative VAN ZANDT. What about concrete, Doctor?

Dr. MILLS. In concrete, depending on the gamma ray and kind of concrete, about 3 or 4 inches are required to reduce the gamma rays by half intensity.

Some of the gamma rays and neutrons are very clever, you see, and can dodge all of these things trying to trip them up and get clear through. On the other hand, alpha and beta particles really stop. If you get to the end of their range, they are completely stopped.

Representative HOLIFIELD. What is their effect if they hit human tissue?

Dr. MILLS. The gamma ray essentially converts itself into fast-moving electrons, and the fast-moving electrons then serve to ionize the atom in the tissue, or the molecule. I am coming back to that in just a second.

The neutron is a neutral particle with no electric charge, and on its own hook, then, has no electrical interaction; so it cannot ionize matter directly. It has a nuclear force associated with it, so it can run into the nuclei of matter.

What a neutron does is, it sails along through matter, dense matter—I am sorry, not air—distances like 3, 4, or 5 centimeters, and bumps into a nucleus with its nuclear force. It just does not see electrons, does not touch them. That makes this nucleus take off and go along at high speed, and it is now a charged particle. It has gotten a severe bump, and it is moving fast, so it is ionizing just like this alpha particle ionizes.

So, the neutrons in water, say move distances like 1 to 3 centimeters. Finally, after many collisions, the neutron stops, and nearly always it will be absorbed by nuclear forces, sucked in and made part of the group inside a nucleus. Usually, this nucleus, after it has eaten this neutron, feels unhappy and wants to do something about it—it feels that perhaps it made a mistake after all—and it will try to remedy the situation usually by emitting a beta particle and changing this neutron, say, into a proton. In doing this, the whole nucleus is disturbed, and the general effect is not only to eventually emit a beta particle, but also to emit gamma rays. So, when a neutron is captured, the induced activity, or secondary radiation created by this step, is to produce gamma rays and beta rays.

I wanted now to come back to what all of these things do.

What I have tried to show is that all of these particles eventually produced ionization, which means they break up the electrical structure of matter. They have knocked the electron out of the atom, out of the molecule, and the molecule may break up into fragments. It is believed, in general terms, that biological damage results when some of these fractured molecules go back together the wrong way.

Chairman DURHAM. If a hospital or a doctor would reecive a patient, and he had an overdose of radiation, how quickly could they determine whether it was alpha, beta, or gamma rays that poisoned the man? Or could it be done?

Dr. MILLS. I do not know whether or not it could be done, and although I am not a medical doctor, I believe that it makes very little difference insofar as treatment is concerned. One has to be a little careful here. There is external radiation and internal. Alpha rays do not get through the skin, because they do not get through the layer of epidermis that is no longer living, and, therefore, it does not matter if it gets cooked a little by the alpha particle. They do not get through that into the living skin, and, therefore, you can stick your hands in alpha rays and nothing will happen.

Chairman DURHAM. Is it important to identify the type of radiation in regard to the treatment?

Dr. MILLS. I think if I could just go along, maybe it will all come out in the wash here.

The way these things then affect matter, they ionize material, they break it up, and then the material will recombine in the wrong way, and you then have a foreign chemical substance somewhere in the cell, something bad for the cell. I do not know really enough about this part, except to give the rough notion; the point being that alpha particles in the air, for example, produce about a million ion pairs per centimeter of air. That is, along the path of alpha particle goes in air there are all these fractured atoms, and if you count them, there will be a million ion pairs, or 2 million total fragments left behind. A beta particle makes only about 50 ion pairs per centimeter, although it may produce the same total number of fragments.

The qualitative understanding of the reasons that alpha particles are more damaging than beta particles, is directly related to the greater density of fragments in the case of the alpha particle.

I have probably said more than I really know as to how these effects occur.

3. Radioactive decay

Now, I wanted to talk about radioactive decay, and then talk about the roentgen and the curie.

First of all, there are radioactive atoms. There are some occurring naturally in nature. There are others that are manmade, either with electrical machines, or with nuclear reactors, or with nuclear weapons.

Generally speaking, these radioactive materials decay, and the first thing I shall say is this: That the danger they produce has to do with the ultimate production of ionizing radiation, usually directly.

Perhaps one of the simplest cases—I wanted to put down the strontium chain. Consider the nucleus, krypton 90, which is one of the fission fragments. It can undergo radioactive decay, emit an ordinary beta particle, electron; and it does this on the average within about 33 seconds. As it does this it changes over into rubidium 90.

Let's talk briefly about what is meant by radioactive decay. I think an analogy that may be helpful is this one:

We have this krypton nucleus here, and it is thinking about ejecting this electron. It has not done it yet. It has a certain chance—in fact a 50–50 chance to do this within the next 33 seconds. It is trying to do it, but it has not done it yet. If it does not do it, then it is just as good as if nothing had ever happened. It is not penalized at the end of the 33 seconds for not having emitted the beta particle before.

Again, it is very much like a person running blindfolded through a woods. His chances of running into a tree next is not affected by

the fact he missed all the trees in back of him when he was running along.

This is the essential reason, then, that radioactive decay is exponential in character. The fact that the remaining nuclei have lived, all of this time up to now does not either increase nor reduce the probability that in the next period of time they will decay. One that has already decayed, of course, is now a different substance, and cannot decay again in the same way. But if you went back to the period just before it decayed, its chances of decaying, say, in the next 33 seconds, in this case, was just the same a year ago as the chance of a not-yet-decayed fragment now decaying in the next 33 seconds. It is not prejudiced by the past. The chance of its doing something is always the same until it does it and then it is not the same thing any more. It is something new.

Senator BRICKER. When krypton decays and gives off the beta rays, what is the remaining substance?

Dr. MILLS. Rubidium 90.

I was not going to write this whole chain down, because I was trying to avoid too many symbols.

Senator BRICKER. There is no other isotope of crypton left?

Dr. MILLS. No, sir; crypton has gone away entirely, and there is a new chemical element. The new chemical element has the same number of neutrons and protons total, but essentially one of these neutrons is changed into a proton, and you see that determines how it juggles the electrons. The whole juggling of electrons is what we know as chemistry.

Senator BRICKER. And the remaining rubidium remains stable?

Dr. MILLS. No, the rubidium does not. I will write down the whole chain for you, if you give me a minute.

Representative VAN ZANDT. Is this krypton related to the krypton taken from the atmosphere?

Dr. MILLS. No, this is not the naturally occurring krypton in the atmosphere. I must say I do not know, but it is a different isotope and has a different number up here [indicating]. It has the same number here [indicating]. I do not need to write krypton at all. I could just say Z is 36, and give the meaning. No one does that because we are not used to thinking that way. I would just like to write down this chain.

We have krypton 90, atomic No. 36. That goes to rubidium 90, and its atomic number is one greater, 37, and this takes about 33 seconds.

Rubidium 90 goes to the famous strontium 90, and that has atomic No. 38. There is another beta particle emitted, and this takes 2.7 minutes on the average to go from rubidium to strontium.

Representative HOLIFIELD. Will you please use the microphone, Dr. Mills?

Dr. MILLS. Yes, sir; I beg your pardon.

This goes to yttrium 90, atom No. 39, which is also nonstable. It decays emitting beta particle, and in about 65 hours—these are all half lives I am writing underneath—which goes finally to zirconium 90, atomic No. 40, and this one is stable.

Representative HOLIFIELD. Now is a good time to describe what half life is, and give the persistence of strontium 90.

Dr. MILLS. Yes; I left that one out. Thank you.

Representative HOLIFIELD. That is the one I do not want you to leave out.

Dr. MILLS. Right you are; yes.

Representative HOLIFIELD. You wrote it. Will you say it?

Dr. MILLS. Yes, sir. The half life of strontium 90 is 28 years.

Now, this particular chain is of special interest in the hearing, so I thought it would be helpful to put it down.

The meaning of half life is this: if I have a substantial quantity of material, that at the end of a time equal to a half life, half of it has decayed, and I have only half of it left.

There is also a quantity called the mean life, which says instead of reducing the amount by one-half, it is reduced to 1 over *e* of its value (e is 2.718). The mean life just makes calculation easier, although the half life is easier to think about.

Chairman DURHAM. What is left has the same half-life as before?

Dr. MILLS. Yes, sir.

Chairman DURHAM. Has the same 28 years.

Dr. MILLS. If I imagine I have an amount here, and wait a half-life, this is transformed. Of course, it is all mixed up. You do not know which one is really going to do it. But this stuff is now rubidium, and this is krypton. If I wait one more half-life this will transform. So I now, at the end of 66 seconds have a quarter as much as I did at the start. If I want another half-life, this much will transform, and at the end of 99 seconds I now have an eighth as much as I did at the start, and so on. It just keeps right on doing this. So once it starts to go, it goes quickly.

What is implied here—if I suddenly make some krypton, then in a relatively short time I have made strontium. That is, this (indicating) has gone to here (indicating), and practically all of it has, you see, at the end of a couple of minutes—nearly all of it is over here in the form of rubidium. I wait, say 10 to 20 minutes, and practically everything is strontium. But now the strontium persists for a long time. I have to wait 28 years to get rid of strontium.

Representative HOLIFIELD. Twenty-eight years to get rid of half?

Dr. MILLS. Yes, sir.

Representative HOLIFIELD. And 28 years to get rid of half of what is left?

Dr. MILLS. Of half of what is left. So at the end of 56 years, I have a quarter as much strontium as I have at the beginning.

Representative HOLIFIELD. How long does it take for it to completely decay?

Dr. MILLS. Forever.

Representative HOLIFIELD. Forever?

Dr. MILLS. But there is not much left after a while.

Representative HOLIFIELD. Krypton 90 is in form of a gas, it is not?

Dr. MILLS. Yes, sir.

Representative HOLIFIELD. How about rubidium-90?

Dr. MILLS. Could I describe what occurs—if this fission fragment were produced in air—let's imagine that—then this is not only a gas, but it is a noble gas, it does not react with things chemically.

So when it finally decays there has been some time—I have 33 seconds for my krypton to run around before it changes into rubidium. The rubidium is now an isolated rubidium atom, just sitting out in the

air without any friends around to speak of. It will probably make friends with an oxygen atom in the air and make a compound, but it is a single isolated molecule.

Most of the chemical substance we think of, we think of good bits of them, large amounts. This fragment produced in air we believe to produce quite small particle size material.

Representative VAN ZANDT. What is the size of the particle?

Dr. MILLS. First of all, I believe this will be mentioned later, but sizes of the order of 10 to the minus 6 centimeters, like a hundred of these things will be joined up and flitting loosely in the air.

Representative HOLIFIELD. Doctor, in the explosion of a large nuclear weapon, while the individual particle is small, there is a tremendous number of those individual particles?

Dr. MILLS. Yes.

Representative HOLIFIELD. That are transferred?

Dr. MILLS. Yes, sir.

Representative HOLIFIELD. Is it not true that this same krypton 90 can be emitted in a gaseous form from a reactor?

Dr. MILLS. Yes. Well, it is harder to do it in a reactor. At least the reactors we want do not immediately breed, you see, they keep everything locked up. That is the big problem.

Representative HOLIFIELD. That is true, but we do have to take preventive measures to keep that from escaping over the atmosphere?

Dr. MILLS. Yes. I was going to mention that. You hold it usually for times like several months. This is a time between changing fuel elements. The old fuel element will have the fissionable material you put into it, and also the fission products in running the reactor, or you have taken time in the reactor for this decay change, in most cases to occur, and essentially you have strontium left, rather than krypton.

Representative HOLIFIELD. What form is the strontium when you get to this point? Is it in the form of a chemical or gas?

Dr. MILLS. The strontium is not a gas. It is probably combined—well, it depends what is in the fuel element. It may just be sitting there as a single isolated strontium atom, say, surrounded by uranium atoms. It might react with other fission products. Or if, for some reason, it is water, if you had a homogeneous reactor with uranium in it, the strontium might form strontium oxide by stealing some of the oxygen from the water molecules.

Representative HOLIFIELD. Any strontium emitted from a weapon is in such a form that can be absorbed by vegetation and ingested into animals, transferred to milk or to eggs, and then deposited in the human body by eating these substances, or drinking the milk, and its half-life persists regardless of the form it is in?

Dr. MILLS. Yes, sir.

Representative HOLIFIELD. When it goes into the human body, it goes into the bone, ordinarily, does it not?

Dr. MILLS. I would rather not——

Representative HOLIFIELD. And it continues the emission of particles at that point?

Dr. MILLS. That is correct. You see the nucleus just lives undisturbed essentially by what the electrons are doing. So all of these chemical changes do not affect nuclear half-life, the decaying, or the emitting of beta particles.

The sequence of events you mentioned I have not really brushed up on, and I believe that testimony comes later. It certainly sounds correct to me, but I would not like to prejudice a later speaker by commenting on that.

Senator ANDERSON. You did say there was a possibility that krypton could come from reactors?

Dr. MILLS. Yes, sir. I was about to get to the fission process. There is a different krypton which is made. There is more than one krypton isotope made, and some of them are longer-lifed, although more radioactive than krypton 90.

Senator ANDERSON. Is there any way we can find out, for example, what type of krypton a reactor would develop?

Dr. MILLS. Yes, sir. We can not only find out, I believe we know.

Senator ANDERSON. Do you know whether a pressurized water reactor puts out the type of krypton you have there in that diagram?

Dr. MILLS. Yes, sir, it puts out this kind. I beg you pardon. By "put out," I mean it produces it. Whether the krypton gets out of the reactor or not is a second problem.

Senator ANDERSON. I understand that.

If it does get into the atmosphere, that kind of krypton leads to strontium 90?

Dr. MILLS. Not in every case.

Senator ANDERSON. You see the difficulty people have, when we ask, "Does this reactor do it?" "Not in every case."

How do we get to know if it ever does it?

Dr. MILLS. Let me go just a little longer. I am going to get to that next in the fission process, and fission fragments.

Senator ANDERSON. All right.

Representative VAN ZANDT. I would like to ask the doctor about strontium 90.

Dr. MILLS. Yes, sir.

Representative VAN ZANDT. Is it not possible that strontium 90 when in the atmosphere can be, in addition to gas or water, a metal?

Dr. MILLS. Well, it is nearly always chemically joined up with something in the atmosphere. It is certainly possible, yes, sir, but very unlikely.

I took the time to write something down. So far, I had mentioned how matter looked, and how these nuclear particles charging around through it can break up atoms and molecules, and then they may rejoin into a new kind of atom, or molecule that causes trouble if it is in a human body. You helped me point out that the radioactive property of the material is not affected by the state of chemical combination; that it can go through very many steps and continue to be radioactive until it actually decays.

One other thing I meant to say about this chain here is that the decay of the yttrium takes place very soon after the decay of the strontium. Therefore, if the strontium, say, is ingested, there is very little chance that the yttrium will be ejected in this short time. So that the proper way to view the total amount of energy deposited in the body is by adding together the energy of the strontium beta ray and the yttrium beta ray, and this is what is usually done.

Representative HOLIFIELD. Do they both have the same property of damage to human tissue?

Dr. MILLS. Both beta rays have the same property of damage to human tissue. The importance of strontium is that it does tend to go to the bone. It is like calcium in its chemistry. The importance of yttrium is that it just cannot get out of the bone in time. So it is almost certain to deposit its energy there along with the strontium.

Representative VAN ZANDT. Doctor, what part of the human body attracts strontium 90?

Dr. MILLS. We all—first of all, this is a little out of my field—but we drink milk, and so on, to get calcium because this is what our bones require. There is also certain turnover of calcium in our bones. The strontium is chemically not identical to, but very similar to calcium, and the body does not always decide it is not calcium, so it slips up and lets some get in. This is a very complicated medical problem which I do not know much more than that about.

Representative HOLIFIELD. We are going to go into this field in detail later on in the hearings, as you know.

Dr. MILLS. Yes, sir.

4. Radiation dosage

I want to say briefly what a roentgen and curie are.

The roentgen was originally defined in a rather complicated way, but it has now been defined in a simple way. At least a physicist can always calculate a roentgen equivalent physical, called a rep. That really means nowadays 93 ergs of energy—which is an energy unit like a kilowatt-hour, only a different one——

Representative VAN ZANDT. A measure of energy.

Dr. MILLS. A measure of energy, 93 ergs of energy deposited per gram of tissue, and that is a simple thing. That is energy out of a radiation field deposited in a gram of tissue.

There is another thing called roentgen equivalent man, "rem," for which beta rays and gamma rays is essentially the same as rep, but the rem is supposed to measure the biological damage rather than just the energy. It turns out, as I explained in the case of comparing alpha particles, and beta rays, that alpha particles are more damaging than the beta rays.

There is, finally, a thing called a relative biological effectiveness (RBE), which the biological people have been working to measure and identify, and essentially the amount of biological damage is given by the product of rep, that is, the amount of energy you put there, and then by the RBE, relative biological effectiveness, which says how damaging that energy is per unit of energy.

For beta and gamma rays, the RBE is 1; for alpha particles it is taken to be 20; and for protons, it is taken to be 10.

There is a list of relative biological effectivenesses for different kinds of radiation, which is used by people in physics laboratories to estimate dosages, and to see they are carrying on safe operations.

These things are revised from time to time, and I am not enough of a biologist to be able to say more than these qualitative indications of how it works.

The other unit that you wished me to define is the curie, and the curie is 37 billion disintegration per second. This is the definition of a curie. It used to be the number of disintegrations of a gram of radium. The number sticks but the definition is used more widely.

To give one some feeling about this: If one has a source producing 1 curie of 1 million volt gamma rays per second, and stands 1 meter away from this source, you will accumulate a biological dose of approximately 1 roentgen of radiation each hour. One thing about the dose, it is an energy per unit mass; so that you could, for example, give the tip of your finger an enormous dose, and it would hurt, all right, but it would not be really a fatal thing. It would be like hitting it with a hammer or getting it burned.

If your whole body receives radiation, then a much smaller dose is dangerous, and roughly, a dose of 400 to a thousand roentgens is likely to be fatal if given to the whole body.

Representative HOLIFIELD. Is it not true that that amount is not applicable to every human being?

Dr. MILLS. Your statement is correct. This is a statistical thing, and the proper way to say it can be quite complex. Also, it is impossible to get volunteers to get good statistics and indirect inference from animal experiments to human effects is necessary.

Representative HOLIFIELD. Is it not true also that the amount of lethal dose for children would be much less than for an adult?

Dr. MILLS. I do not know the proper answer to that question, sir.

Representative COLE. Mr. Chairman, I do not understand the witness' response. You asked him if it were not true, a certain hypothesis, and he said no. Now, with respect to whether the same dosage would affect all people the same——

Dr. MILLS. I beg your pardon. Different people quite clearly have different tolerances for different dosages, but the more complete experiments are usually carried on with laboratory animals, so you can get statistics. And a feeling how wide the swing is of the different tolerances of different individuals to a fixed amount of radiation is usually done with laboratory animals, not people. But it does fluctuate quite a bit.

For example, some people will get quite ill, it is believed. They have not done this with people, but it is believed to be so at 200-roentgen whole-body radiation, and other people would perhaps survive 400-roentgen whole-body radiation.

Representative HOLIFIELD. But, in any event, whether they survived or not, the radiation would be harmful to tissue and would result in a possible destruction of the cells of the body, and the ability to recreate those cells, and, therefore, it would be considered to be harmful regardless of the amount. Is that true?

Dr. MILLS. You will have to ask a biologist. I believe, though, that Dr. Durham said that any quantity of radiation is considered to be harmful. I am not expert on these things.

The other way, of course, one can have trouble with radiation we have already mentioned. You can ingest a substance, take it into your body, that is radioactive, and then it can go to a more sensitive place, or to a less sensitive place, and decay, and in decaying produce the radiation damage.

Alpha particle emitters are a particular case in point. The alpha particles are the most heavily damaging, but ouside the body they do not get through the skin. Inside of the body many of the alpha emitters seem to go to the bone, and then they sit and bombard the bone marrow.

Representative HOLIFIELD. The alpha particles do not have penetrating quality, and it results in skin lesions and burns?

Dr. MILLS. No, they do not.

Representative HOLIFIELD. What I said is true?

Dr. MILLS. Yes.

Representative HOLIFIELD. And your gamma rays can penetrate the body?

Dr. MILLS. Clear through.

Representative HOLIFIELD. Or penetrate a cement wall?

Dr. MILLS. Yes.

Representative HOLIFIELD. What is the difference between the neutron effect and the gamma ray effect?

Dr. MILLS. Well, the alphas—let me go quickly in sequence—the alphas do not get in, really, to the skin. The beta rays get onto the living skin and can cause trouble, but not deep into the tissue at all. The gamma rays of appreciable energy can essentially go anywhere in the body, and if a beam of gamma ray comes in here [indicating], there is a certain number of them that come clear out the other side, and some of them run into something inside. And a similar sort of thing can be said for neutrons, except a little bit depending on their energy.

One would think, for example, if you were irradiated from outside with neutrons, only a layer of an inch or so would get the brunt of the radiation, and maybe things deeper inside would have a much weaker neutron band. The neutron does most of its trouble by creating secondary radiation, usually gamma rays. Although the gamma rays they create might be produced here, those gamma rays, in turn, can be diffused through the whole body. So even though the neutrons tend to be stopped near the surface, it does irradiate a good deal of the body, not localized near the surface.

I wanted to say one other thing. Radioactivity is usually spoken of in quantity according to the word "curie." A given weight of matter will have a certain number of atoms in it. Since each of those atoms will decay with certain half-life, you can connect-up the half-life and the quantity of material and the kind of material. The kind has to do with how many atoms per given weight, and, therefore, so many curies of any given substance also corresponds to a certain given weight of that substance.

In the particular case of strontium 90, a microcurie, one-millionth of a curie, corresponds to one-billionth (one over a thousand million) one-billionth of a gram of strontium 90. Just to give one piece of orientation.

III. FISSION AND FUSION

I wanted to quickly mention the fission process, and the fusion process. This has to do with part III, really, of your outline.

1. *Fission*

The fission process is spoken of this way: U-235 plus a neutron makes fission fragments, usually 2 in number, plus 2½ neutrons.

Now the clue that something is quite complicated, is the 2½ neutrons. There is either a whole neutron, or no neutron. There is not even a half neutron. This means some of the time you make 3 neutrons, and some of the time you make 2. And indeed the thing is quite complicated.

There are about 170 different nuclear species produced if you fission quite a bit of material and then count things up.

Representative HOLIFIELD. And all of which vary in half-life?

Dr. MILLS. And all of which vary in half-life.

Furthermore, they have chains, even as if I made this [indicating], this, and this, each separately, and each decayed its own way. But it is much worse than that.

Not only do I make a number of different chain leaders—say this is No. 1 man—I make a variety of these. There are about 70 of these chains. But then each of these chains run this way [indicating].

Furthermore, in the fission process—I do not know if this is a good one, but I can assume so—sometimes the fission will make the second member instead of the first member of the chain, or sometimes even a third member. So I have all these chains, and I have things starting at the front which are the mainline, but then I have now and then a fission that will cheat and skip that [indicating], and just make this one [indicating].

The products then are quite varied in number and complexity. There are 35 different chemical substances, 95 different masses, and 170 different isotopes.

2. Fusion

One can contrast that with fusion. There are some more fusion reactions one can write down, but these are usually considered the most interesting.

This is heavy hydrogen, D for deuterium, is the conventional symbol. The deuterium nucleus has a neutron and proton in it. And one electron outside makes the complete deuterium atom.

The deuterium and deuterium reaction makes helium 3 which is the neucleus of the helium atom, but shy one neutron; and also an energetic neutron.

Sometimes deuterium plus deuterium reaction goes to make tritium, which instead of having 2 protons and 1 neutron like helium, has 1 proton and 2 neutrons. It is extra heavy hydrogen, and weighs three times instead of twice as much as regular hydrogen plus an ordinary proton, the ordinary nucleus of the hydrogen atom. Then I can also react deuterium with tritium to make normal helium plus a 14 Mev. neutron. The 14 means the energy at which the neutron comes scooting out of here [indicating]. This neutron from the DD reaction is about 2 Mev. in energy.

There is one other interesting thing, deuterium in water.

It occurs in nature to a small extent. Most of the hydrogen in nature is ordinary hydrogen, having just a proton and electron. But heavy hydrogen occurs with the other hydrogens to the extent of about a little more than a hundredth of a percent. If one calculates the amount of energy you can get from a gram of water if you react or fusion the deuterium in that gram of water, it turns out to be about 100 times the amount of energy you can get from a gram of fuel oil by burning the fuel.

Since there is a tremendous amount of water in the ocean, all of which has this trace of deuterium in it, it means the oceans are sort of like oceans of fuel oil, only about 100 times as good in terms of total energy reserve. I understand there have been a few problems in getting at this energy.

The other comment you wanted me to make—am I skipping along too fast?

Representative HOLIFIELD. No.

Senator ANDERSON. Did you say if the ocean were filled with deuterium, as a fuel it would be 100 times more valuable than if it were filled with oil?

Dr. MILLS. It has potentially 100 times as much energy. I just say it that way because apparently there is quite a bit of work in research and development to be able to burn the ocean.

Senator ANDERSON. I did not say we had it solved. But if you did have it solved, that is the fact?

Dr. MILLS. Yes.

Senator ANDERSON. One hundred time as much energy in the ocean, if filled with deuterium as it would be if the present water could be scooped out and the areas filled with oil?

Dr. MILLS. That is correct, yes, to use it all.

Representative VAN ZANDT. It is contingent upon a hundred million degrees of Fahrenheit.

Dr. MILLS. Yes. I was going to cycle a little bit.

To make these reactions go in a useful way people feel they have to be thermonuclear reactions. That is, you get the materials so hot that these particles will run into each other and fuse and make the products and the energy you are after. The temperatures one talks about are 100 million to 1,000 million degrees to do this. So people who are practitioners of this art are likely to get their fingers burnt if they are not careful.

This is a difficult but very interesting development, and I am sure a very important one, because it offers to humanity the possibility of an unlimited energy reserve.

Representative VAN ZANDT. How close close are we to fusion?

Dr. MILLS. I was going to answer that in a little complicated way. Maybe I should now.

The current situation, in rough terms, is that the fusion process is not yet at the state of physical practicability. A physical demonstration of the controlled fusion process is not yet to the state of the 1942 Chicago fission reactor.

Representative HOLIFIELD. You mean fission.

Dr. MILLS. Thank you. Fission reactor, first of the chain reactors.

Representative VAN ZANDT. I imagine you have reference to Dr. Fermi's first atomic pile.

Dr. MILLS. Dr. Fermi's CP-1, the first Chicago pile. Of course, that one is rather modest compared to fission reactors people are thinking of now.

So there is, first of all, about a 14-year delay at least, if you say the developments are of comparable difficulty.

My own feeling is the fusion development is somewhat more difficult, and I tend to add another 5 years to that. So that would put fusion about 20 years behind fission in terms of potential use and economic use in particular.

Now, Mr. Davis, of the Division of Reactor Development of the Atomic Energy Commission has been studying the economic feasibility of the fission reactor, and he has estimated that as of about 1970 the fission reactors will begin to compete effectively with chemical plants, coal or oil-burning plants, for economic electric power production in

stationary plants. So if you say that one of the things you would like to get from the fusion process is economically competitive, stationary electric power, this would infer that with this about 20-year lag I have put in, it would be in the 1990's before you might expect to worry about the economic impact of the fusion process.

Probably it would be a little longer, because we all believe, I think, that the fission process will take hold sooner than that, and it will ease the economic pressure, and conserve conventional fuels. The fission process itself then may add some additional delay by taking some of the economic urgency away from the fusion development.

Representative HOLIFIELD. Will you go to the radiation comparison between fission and fusion?

3. Fission and fusion radiation

Dr. MILLS. Yes. I did a rough-and-tumble estimate, and I would like to reiterate this is crystal gazing.

There are some things you can say on the basis of the fundamental reaction, some things you can guess at, but it is awfully hard to compare this reaction (fission) with this one (fusion) in practical plants, because there is not any practical plant like this (fusion). The possible radioactive dangers, therefore, first of all, may be very different than you think of. They may be nonexistent. There might be a danger of an entirely different kind that no one has thought of at all, but would have the main importance.

Representative HOLIFIELD. You are referring to plants to produce energy, are you not?

Dr. MILLS. Yes.

Representative HOLIFIELD. I am not referring to that.

Dr. MILLS. Beg your pardon.

Representative HOLIFIELD. I am referring to the present use of fission and fusion in weapons.

Dr. MILLS. I see.

Representative HOLIFIELD. And the comparison between the radioactivity of the different fusion products and the fission products. I realize that is not in your field, but as long as your talk is on the background of radiation and radioactivity, I thought you might make a general comment on that.

Dr. MILLS. I would like to make a very general comment of two kinds.

First of all, the fission process itself produces directly radioactive material, namely, these fission fragments, a large variety of them, a very complex set of them.

These fusion reactions I have listed here—of all the things they produce only tritium is itself radioactive. It decays slowly to helium 3, which is stable.

Chairman DURHAM. Is there any difference as to the stability of it, whether it is a gas or whether it is a solid?

Dr. MILLS. No; its radioactive decay continues no matter what form it is in, gas or solid. You can make tritium water, for example. It does not matter.

Representative HOLIFIELD. At the present time fusion has to occur after fission occurs; it is dependent upon the heat developed by fission, is it not, to bring about fusion, Doctor?

Dr. MILLS. If you will forgive me, sir, I would rather not comment on that question.

Representative HOLIFIELD. All right.

Representative VAN ZANDT. Dr. Mills, what about the penetrating strength of the radiation produced by fusion?

Dr. MILLS. The only direct production of radiation by fusion is tritium, which produces about a 10-kilovolt, very weak beta particle, and that beta particle cannot penetrate the skin.

Senator BRICKER. What is the half life of tritium?

Dr. MILLS. About 12 years. However, fusion does produce neutrons, as also does fission, and these neutrons can be captured in the surroundings one way and another, and activate things.

For example, neutrons captured in sodium will produce sodium 24, which has a half life of about 15 hours, and produces beta and gamma rays, and the gamma rays are rather penetrating.

So if there were some reason—for example, if both of these things occurred with sodium, these neutrons here from fission would make a certain amount of radioactivity, and so would these from fusion. So that the induced activity might possibly be comparable.

You see, I have 2 neutrons here, and 2 there.

There is finally one other thing you can say. Generally there does not have to be things that these neutrons will react to, and they can be captured more or less harmlessly in the air. So that for many practical purposes, there is essentially no radioactivity associated with the fusion process.

Finally, the fission fragments are of such a great variety that if you were now to switch from the general problem to a machine, there are very many different chemical things you have to keep track of and prevent leakage—for example, if you spill them there are many varieties of things you would have to pick up. It is hard to get them all. With fusion, by making the machine out of the right thing, you may make it so these neutrons essentially cause no trouble, or you can select a material that produces one kind of neutron-activated product that is simple to clean up and pick up.

Representative VAN ZANDT. Do I understand you now that fusion will produce the alpha, the beta——

Dr. MILLS. No, sir; fusion will not. Fusion just makes these things here [indicating] of which only tritium is radioactive. Fission produces an enormous variety of products, and both gamma and beta rays come pouring out of the fission fragments.

Chairman DURHAM. From a distribution standpoint, Doctor, fission, and also the thermonuclear, would you hazard an opinion as to which one is more easily distributed in the air and on the ground? Would there be any difference?

Dr. MILLS. The fission products, there are some volatile ones that are carried around easily in the air. Some will dissolve in water. There is such a great variety.

The tritium produced in fusion would normally be a gas unless it combines with oxygen to make water. So it can blow around in the air as a gas or it can combine with oxygen and flow in water. Tritium is a radiological hazard, but generally speaking, nothing like fission products. The rest of these things are not radioactive. They are gases. Helium is a gas not chemically reactive, not harmful chemically, and, of course, not radioactively harmful.

Representative HOLIFIELD. Are there any further questions?

Had you finished your general statement, Doctor?

Dr. MILLS. Yes, sir; I had.

Representative HOLIFIELD. Dr. Mills, the committee appreciates you coming here from California to make this statement. We know how complicated it is, and we do feel you have given us in layman's language an understanding of this in about as simple a form as it can be made.

You will have access to the transcript so that you can be sure the reporter has caught properly your symbols and other references, and for the purposes of correction of anything which may not be clear on the record.

Dr. MILLS. Thank you, sir.

Representative HOLIFIELD. Thank you very much, Dr. Mills, your submitted material will be inserted in the record at this point.

(The matter referred to is as follows:)

STATEMENTS ON TOPIC II RADIATION AND RADIOACTIVITY, AND TOPIC III FISSION AND FUSION REACTORS, FOR THE JOINT COMMITTEE ON ATOMIC ENERGY

Prepared by Mark Mills, University of California Radiation Laboratory, June 1957

Mr. Chairman and gentlemen, I welcome the review of the Nature of Radiation and Its Effects on Man, which you are conducting in these hearings during May 27 through June 7. I want to thank you for the honor of inviting me to address you. I will be glad to answer questions to the best of my ability.

II. RADIATION AND RADIOACTIVITY

In order to tie together the results of my discussion of radioactivity, I will include some remarks about the biological effects of radiation. This is only to give perspective, and I wish to emphasize that I am not a radiologist nor a medical doctor. In making these statements about the biological effects of radiation, I am merely repeating some of the things medical experts tell physics people so that, in turn, the physicist can design adequate shielding and take suitable precautions when working with radiation and radioactivity. It is my understanding that a careful and expert review of the biological effects will be a portion of the subsequent hearings.

1. Radiation and radioactivity

Radiation consists of very energetic fast-moving particles. These particles are usually given the name of alpha rays, beta rays, and gamma rays, and sometimes one has to be concerned about radiation consisting of neutrons.

There are a number of different sources of radiation. The special manmade electrical machines can accelerate a particle of ordinary matter to such high speeds that it deserves the name of, and in fact is, radiation. A neutron chain reaction can be sustained in a nuclear reactor and produce fission products which, in turn, emit beta and gamma rays. Nuclear weapons can produce radioactive materials, which in turn produce beta and gamma rays.

Radioactivity is the name given to the process whereby an atom produces radiation. A material which emits radiations is called radioactive. Radium is probably the most famous example of radioactive material.

In undergoing radioactive decay, the radiation is actually emitted from the nucleus of the radioactive atom. Furthermore, there is a mother-daughter sequence. The mother atom emits the radiation and in so doing is transformed automatically to the daughter atom. Usually the mother and daughter atoms are different chemical substances, although in those cases where the gamma rays are emitted, the mother and daughter are the same chemical substance.

It turns out that the radioactive decay of a mother nucleus to a daughter nucleus can be described by the term "half life." At the end of a given period of time, for example in the case of radium, at the end of 1,600 years, half of the mother substance has transformed into the daughter substance. Since the emission of radiation is the step that makes this transformation possible,

a given quantity of material can produce very intense radiation provided it has a short half life, or very weak radiation provided it has a long half life. The half lives of radioactive transitions have been measured and cover an enormous range. For example, the half life of uranium 238 is approximately 4 billion years. Whereas the half life of krypton 90 is about 33 seconds.

To visualize the meaning of half life a little better, it may be helpful to say the following. At the end of a half life, there is half as much material present as there was in the beginning of the half life. If we start with 1 pound of a given radioactive substance, at the end of the first half life there would be one-half pound, at the end of another half life there would be half this amount, or one-quarter pound, at the end of another half life there would be one-eighth pound, etc. A very long time would be required to get rid of all of the original material in this way, but at the end of only 10 half lives there is only one one-thousandth of the original material left, so that for most practical purposes practically all of the material has disappeared at the end of a few half lives.

2. Radioactive decay cannot be disturbed

Nothing disturbs in any way the radioactive decay of a radioactive substance. For example, if one had fuel oil containing radiocarbon and radiohydrogen, and burned this fuel oil, the smoke would carry the same radioactivity and to the same extent as was previously present in the fuel oil. The radioactive process cannot be speeded up, nor slowed down, but depends only on the nature of the radioactive substance involved. Fundamentally, this is due to the fact that the radiations are emitted from the nucleus of the atom, and all of the chemical processes like burning, melting, boiling, etc. disturb only the outermost electrons of an atom and affect the nucleus hardly at all.

As another example, the radioactive isotope strontium 90 is formed very quickly by the successive beta radioactive decay of the fission fragments krypton 90 (half life 33 seconds) which turns into rubidium 90 (half life 2.7 minutes) which decays into strontium 90 (half life 28 years). If one imagines that the krypton 90 is produced in an atomic explosion, the strontium 90 will probably be produced in the air. It will then probably form strontium oxide with the oxygen in the air, fall slowly to the ground (fallout), and may then possibly settle into the soil, be absorbed by plants, the plants may be eaten by a cow and some small fraction of the strontium going into the milk, finally, if a person drinks the milk, some small fraction of the strontium will go to his bones (since strontium is similar to calcium in its chemical properties). Despite this long sequence of events, the radioactive behavior of the strontium continues at its regular pace.

3. Penetrating power of radiation

Different kinds of radiations can penetrate different distances through different materials. However, for radiation consisting of a given kind of particle, the depth of penetration in a given material depends only on the energy of that particle, being greater for more energetic particles. For alpha, beta, and gamma rays, the depth of penetration is less in more dense substances than in light materials.

The following is a list of the names and penetrating powers of the different radiations:

The alpha particle is a fast-moving helium nucleus consisting of 2 neutrons and 2 protons tightly bound together. Alpha particles emitted by naturally occurring radioactive substances move at about one-twentieth the speed of light and will penetrate distances of 2 to 5 cm. of air before being brought to rest. They will penetrate about 0.002 to 0.005 cm, in tissue, and since the epidermal protective layer of dead skin on the body has a minimum thickness of 0.007 cm, alpha particles are harmless when the source emitting them is outside the body.

The beta particles consist of a fast-moving electron essentially moving with the speed of light, although just a little less than the speed of light. They can penetrate distances of a few meters in air, or ½ cm. into water or tissue before being brought to rest.

The gamma particles or gamma ray, are really the same kind of thing as light or radio waves, but the energy of a single gamma ray is very much greater, amounting to something like 1 million electron volts. A gamma ray does not penetrate a definite distance into matter, but has a certain prob-

ability of being absorbed. If a large number of gamma rays are fired into matter, after some distance only half of them will remain, and at double the distance only one-fourth of them remain, and so forth. Gamma rays of 1 million electron volts energy are reduced to half intensity by 1 cm. of lead, or by 10 to 20 cm. of water, or 100 to 200 meters of air.

Any of these radiations may have any given amount of energy, but in most cases energies of a few million electron volts correspond to "typical" radiation.

The characteristics of neutrons, deutrons, protons, and other radiations have not been mentioned because they will be of little concern for present considerations.

A signlficent feature of the properties of these various radiations is in their relative danger inside and outside the body. For example, a substance which emits alpha particles does not constitute a hazard outside the body, since alpha particles are not energetic enough to penetrate the epithelial layer of dead skin and reach the living skin. A substance which emits beta rays can cause skin burns and irradiate the tissue to a depth of a few tenths of an inch. This is not likely to cause damage to internal organs. Radioactive materials which emit gamma rays, however, can pass this radiation clear through the body and therefore can irradiate the entire body even though such gamma ray emitting substances are kept outside the body.

Consequently, it is convenient to think of the danger of radiation as dependent upon whether the radioactive material is outside of the body or inside the body. In general, the danger is greater when the material gets inside the body. A dense cloud of a mixture of radioactive materials in the air, such as the complex set of fission products, could pass by an individual and give him a radiation dose throughout his body by means of gamma rays. The cloud might later settle into a water supply and a different individual could drink the water containing the radioactive material and receive an appreciable radiation dose to his internal organs from all three types of alpha, beta, and gamma rays emitted by material absorbed in his body.

4. The effect of radiation on matter

Almost all of the material that we use in our everyday lives: glass, steel, grass, wood, air, human tissue, water, and food are made from groups of atoms called molecules. When a molecule is bombarded by radiation, it may be broken up into fragments consisting of one atom or smaller groups of atoms. These atoms may then remain permanently broken up (for example, by irradiating water one can change some of it into hydrogen and oxygen gas), or the fragments of the original molecule may recombine to form a new molecule. Most of the bad effects of radiation are believed to be due to the formation of new, unsuitable, molecules within the irradiated material.

Radiations are much more effective in producing transformations of this kind than energy in other forms. For example, it has been estimated that a dose of whole body radiation sufficiently large to be fatal to a human being, if applied in the form of ordinary heat would only increase his body temperature by about 1/1000° F. Merely by running upstairs the body temperature is increased more than this amount. Therefore, although radiation does consist of ordinary particles moving with a great deal of energy, it does have special qualitative features:

5. The same kind of radiation always has the same effect

We believe that the same kind of radiation always has the same effect. For example, if tissue is bombarded by a beta ray from strontium or a beta ray from Yttrium, we believe the effect on the tissue is the same. We also believe that the effect of gamma rays and beta rays are the same. It has been observed that alpha rays are more damaging than beta rays. For example, a 5-Mev. alpha particle appears to be 20 times as damaging as a 5-Mev. beta particle when both are absorbed entirely within the same kind of tissue. In general terms, this is believed to be due to the much greater intensity of disturbance along the path of the alpha particle. Since the alpha ray stops in such a short distance (0.003 cm.) as compared to the beta ray (0.5 cm.), it produces a much greater density of disturbed matter along its path.

6. The roentgen and the curie

The roentgen is used as a measure of radiation dose to a physical system. There are essentially two kinds of roentgens of practical importance. One is called the rep, which is roentgen equivalent physical, and is defined to be the

absorption of 93 ergs of energy per gram of tissue. The other is the rem, the roentgen equivalent man, and is intended to measure how damaging the radiation energy is to a biological system. We have already pointed out that for the same amount of energy, alpha particles are 20 times as damaging as beta particles. Gamma rays are considered the same as beta particles in their damaging effects.

For people working around radioactive substances, tolerances have been established. The basic tolerance requires that a worker should receive no more than 0.3 rem per week. Similarly, workers with such substances may inadvertently inhale or swallow some of them, and there are limits set on the quantities of various radioactive materials that may be allowed to enter the body and corresponding limits on the concentration of radioactive substances in the air or in water.

For example, in the case of strontium 90, the allowable amount in the body has been set at 1 microcurie, which corresponds to six one-billionths of a gram. Strontium 90 tends to go to the bone and then irradiates the bone with beta particles. The daughter of strontium 90 is yttrium 90, which is also a beta particle emitter with a lifetime of 65 hours. Sixty-five hours is such a short time that it is generally assumed that the yttrium 90 stays in the bone in the same place in which its parent, strontium 90, was located. Consequently, the dose received by the bone is the accumulated dose of both strontium 90 and yttrium 90.

Since the dose is defined per gram of tissue, it is conceivable that an intense dose to a small region of the body, such as the tip of the finger, of thousands of rem would be analogous to a severe burn, or hitting the end of the finger with a hammer. It would hurt, one might lose the end of his finger, but it would not be fatal or even very serious. On the other hand, a whole body dose of 500 rem can be fatal. The estimates of lethal levels of radiation must be inferred from animal experiments and it is observed that different individuals have different tolerances to a given dose of radiation—therefore, the 500-rem estimate given above for a lethal dose would not apply to everyone. It is believed to apply to about half of the individuals.

The conventional measure of radioactivity is the curie. This is now defined to be 37 billion disintegrations per second. In the case of long-lived radioactive materials, a large amount of material may be required to produce an activity of one curie. Short-lived materials, since each bit of material transforms so much more quickly, can produce a curie of activity with much less of material present. Furthermore, if the product of the radioactive decay is a stable atom, eventually the total curies of activity will decrease just according to the half life involved.

For orientation, a person 1 meter from a 1 curie source of gamma rays, each gamma ray of 1 million electron volts energy, will receive about 1 roentgen of radiation dose for each hour of exposure.

III. CONTROLLED FISSION AND FUSION REACTORS

1. The fission reactor

The fission reactor consists of an assembly of fissionable material arranged so that a neutron chain reaction can maintain a steady rate of fissioning in the machine. The reactor may be used to produce heat, which in turn might be used to produce electricity; there are also research reactors which can be used to produce radioactive isotopes for chemical, metallurgical, or biological research, or used in certain kinds of physical experiments.

The fission reaction itself is a very remarkable one. If a neutron enters the nucleus of U-235, the nucleus will split roughly in 2, producing 2 fission fragments of great energy and also 2.5 new neutrons which can serve to carry the chain reaction further. The same fission fragments are not produced in each instance, and with greater or lesser abundance some 170 fission fragments with 95 different masses and representing 35 different chemical substances are made. These fission fragments are generally radioactive chains, or materials decaying one into another. Of the total energy produced in the fission reaction, about 200 million electron volts per fission, some 13 million electron volts or about 6 percent of the total energy is produced by the radioactive decay of the fission fragments. With the great variety of fission products, a large numebr of different radioactive lifetimes are involved. Consequently, fission products produce sustained radioactivity as the short-lived products decay away, some of the longer-lived products remain. This complex set of products, instead of decaying to one-half intensity every half life does not appear to have a very definite half life, but gradually loses in intensity over long periods of time.

2. The fusion reaction (or controlled thermonuclear reaction)

Since there are at this time no practical machines which produce energy from the fusion reaction, all one can do is write down a number of reactions which have been suggested of interest for the fusion process. Some of these reactions are:

$D+D \rightarrow He^3+n$ (2 Mev.) ---------------------- (over all, 3.3 Mev.)
$D+D \rightarrow T+H$ ---------------------------------- (over all, 4 Mev.)
$D+T \rightarrow He^4+n$ (14 Mev.) --------------------- (over all, 18 Mev.)

The symbols have the following meanings: D is deuterium, the nucleus of heavy hydrogen, and weighs twice as much as regular hydrogen. H stands for ordinary hydrogen nucleus. T is tritium, the nucleus of extra heavy hydrogen, weighing three times as much as ordinary hydrogen. Tritium decays to He–3 with a half life of 12 years, emitting a weak beta particle. He^4 is the ordinary helium nucleus or alpha particle; He–3 is a helium nucleus lacking one neutron and only three-fourths as heavy as He–4. The symbol n stands for the neutron. The energies given right after the neutrons indicate how energetic (energy of motion) the neutrons are when produced. The overall reaction energies are also listed. Clearly, the energies of the neutrons should be usefully captured since they carry a large part of the overall energy produced.

H, D, He–3, He–4 are all stable, T is the only radioactive material (except for neutrons).

In order to achieve these reactions in a useful way (they have been achieved in the laboratory with accelerators but not with high temperatures), temperatures ranging between one-hundred million and one-billion degrees centigrade are required. Nuclear reactions driven by high temperatures are achieved in the stars, and are often called thermonuclear reactions. The same name will be suitable for the fusion reactions if they are achieved in a useful way. Since no material can stand such temperatures, a magnetic field is usually considered as the means to hold thermonuclear fusion materials together. The goal of this area of research is the controlled release of thermonuclear energy.

You will notice that the important source of material for these reactions is deuterium, which is heavy hydrogen, which is the hydrogen in heavy water. Deuterium occurs to the extent of 0.014 percent in natural (ordinary) water, and a little calculation shows that on the basis of deuterium content, the potential energy available from a gram of water is about 100 times as great as the energy available from a gram of fuel oil. Consequently, the world's oceans represent an enormous potential energy supply. If a practical fusion reactor can be found, to make use of the deuterium from the world's oceans, then the energy supply would be the same as if the oceans were filled a hundred times over with fuel oil.

3. The comparative hazards of fission and fusion reactors

Since there is no practical fusion reactor machine, it is very, very difficult to compare the hazards of fission reactors, whose characteristics are at least generally known, with the so-far undeveloped fusion reactor. Anything said here must be considered as crystal gazing. Nevertheless, one can make the following very general statements: The fission reactor produces radioactive fission products and neutrons; the fusion reactor produces only radioactive tritium, and the remaining products are not radioactive. The fusion reaction also produces neutrons. In both the case of the fission and fusion reactor, the neutrons may serve to activate materials in the reactor or in the surrounding area, leading to an accumulation of radioactivity.

The real hazard from power-producing machines is due to the possible escape of radioactivity from the machine leading to contamination of the surrounding area. If all the radioactivity produced is extremely short lived, then it would decay away before constituting a hazard even if some of it were to be released. It is the delayed, or long-lived radiation, or radioactivity, that is the hazard.

Finally, I would like to point out that the fission products are a very complex mixture, that there are nearly always some of them that have a disagreeable half life, that they represent very many chemical species so some of them are bound to be especially troublesome, and finally, they will be rather hard to clean up because of their very great variety. In addition, the fission products are a direct product of the fission reaction and must be produced if this reaction is used.

In the case of the fusion reaction, the only direct radioactive product is tritium, which is a mild material. Activation of the surrounding structure can be con-

trolled if it is constructed from suitable materials. For this reason, it appears that radioactivity danger from controlled fusion reactors, when they are invented, could very well be much less than danger from the fission reactors.

4. Economic power from fusion

This prediction of a time scale for controlled fusion (thermonuclear) development is difficult and uncertain, and I will assume that economic fusion power is the question of main interest. One may argue as follows:

(1) Currently, fusion has not reached the state of development of the late 1942 Chicago fission pile. This pile is sometimes called Fermi's pile. (Fourteen years or more behind fission.)

(2) Fission itself is not yet economic, but may be so by 1970. (W. K. Davis, private communication.) (Twelve years.)

(3) Fusion development seems to be more difficult than fission development. I do not know exactly how to weigh this, but a 5-year delay seems reasonable (5 years).

(4) Fossil fuel shortage will be eased by fission reactors by the time that fusion techniques are of practical interest. Therefore, the economic pressure for fusion development will be reduced (5 years).

If all these estimates are combined, then:

Practical economic fusion power production will probably not be achieved before the 1990's. It is possible, but unlikely, that this could move up to the 1980's with remarkably good luck.

SUPPLEMENTARY STATEMENT OF MARK M. MILLS, UNIVERITY OF CALIFORNIA RADIATION LABORATORY

PLEASE NOTE.—The written material in part II below is essentially just bibliography. By verbatim abstract of various texts and data tables something like a combined textbook-handbook may be compiled. This possibility is indicated by the notes:

Verbatim (for text).
Copy figure (for diagrams).
Copy table (for data).

General bibliography is indicated separately.

II. RADIOACTIVITY AND RADIATION

A. Atom, nucleus radioactivity

(Includes: Nature of radiation, mass and energy, fundamental particles, radioactivity, nuclear reactions.)

Verbatim (including figures): From: H. D. Smyth, Atomic Energy for Military Purposes, Princeton Press, 1945. Part of chapter I, pages 1–21.

Additional bibliography:

1. I. Kaplan, Nuclear Physics, Addison-Wesley, 1955. Especially chapters 1, 2, 3, 8, 9, 10, 11, 13, 14, 15, 16, 19.
2. E. Pollard and W. L. Davidson, Jr., Applied Nuclear Physics, Wiley, 1942. Especially chapters 1, 2, 5, 6, 10.
3. F. Rasetti, Elements of Nuclear Physics, Prentice-Hall, 1936. Epecially chapter II.

B. Interaction of radiation with matter

(Ionization, energy transfer, penetration, absorption, attenuation, induced radioactivity, secondary radiations, neutrons.)

Verbatum (including figures and tables): From: E. Pollard and W. L. Davidson, Jr., Applied Nuclear Physics, Wiley, 1942. All of chapter 2, pages 10–17; part of chapter 3, pages 18–23 (down to "Applications of").

Additional bibliography:

F. Rasetti, Elements of Nuclear Physics, Prentice-Hall, 1936. Especially chapter III.

I. Kaplan, Nuclear Physics, Addison-Wesley, 1955. Especially chapters 13, 14, 15, 18.

C. The roentgen and the curie

(Roentgen, curie, relative biological effectiveness (RBE)).

Verbatum: From: M. S. Fair, chapter 2.2, volume I, The Reactor Handbook (AECD–3645), United States Government Printing Office, 1955. All of chapter 2.2, pages 629–635.

Additional bibliography: United States Department of Commerce, National Bureau of Standards, Maximum Permissible Amounts of Radioisotopes in the Human Body and Maximum Permissible Concentrations in Air and Water. Superintendent of Documents, 1953. (Usually known as NBS Handbook 52.)

D. Neutron fission and chain reactions

(Includes: fission reaction, chain reaction).

Verbatum (including figures):

(1) From: H. D. Smyth, Atomic Energy for Military Purposes, Princeton University Press, 1945. Parts of chapters I and II, pages 22–39, ending on page 39 at "Availability of materials".

(2) From: The Reactor Handbook (AECD-3645) volume I, Physics. Tables 1.2.11, 1.2.8, 1.2.9, 1.2.10, figure 1.2.13.

Additional bibliography:

E. Nuclear fusion and thermonuclear energy

Verbatum: (None).

Bibliography: R. F. Post, Controlled Fusion Research, Rev. Mod. Phys. *28*, 338 (1956).

Nucleonics, page 23, December 1955; page 42, February 1956.

F. Particle accelerators as source of radiation hazard

Particle accelerators produce infinitesimal amounts of radioactivity as compared to fission nuclear reactors. Safe management of radiation and radioactivity is, of course, required; but there is no hazard to the public.

Bibliography: I. Kaplan, Nuclear Physics, Addison-Wesley, 1956, chapter 21, pages 541–560.

Note.—The bibliography for part III below is given at the end. The material given below is itself an actual insert for the record.

III. CONTROLLED FISSION AND FUSION REACTORS AND THEIR POTENTIAL AS A SOURCE OF HAZARD

A. Fission reactor (nuclear reactors)

1. The nature of fission chain reactors.—(*a*) Description: Geometrically, a nuclear reactor installation is often arranged (starting from the center and working outward) as follows: core region, consisting of fuel, moderator, fertile material if any, cooling passages; reflector and/or blanket, consisting of neutron reflector and additional fertile material, if any; cooling if needed; reactor tank, a substantial mechanical structure containing the core and reflector regions; shielding to confine nuclear radiations inside the core-reflector system (for power reactors the shielding can be ten feet thick and weigh many hundred tons—it represents a substantial mechanical barrier as well as a radiation barrier); reactor room, containing instruments and controls; and containment shell outside the reactor room to prevent escape of radioactivity to the surrounding area if material should escape the shield. The massive shield can serve to protect the containment shell from any mechanical violence originating inside the reactor.

The components of a nuclear reactor installation may be classified into six main parts according to function: basic nuclear system, nuclear control system, heat removal (cooling) system, reactor structure, shielding, and external containment shell.

The basic nuclear system includes the nuclear fuel, fertile material if any, and neutron moderator inside the core and the neutron reflector outside the core. Coolant or structure may provide some of these functions. The basic nuclear system sets up the conditions enabling the system to go critical, and determines the neutron spectrum and neutron economy. A high ratio of fuel (U–235, Pu–239, U–233) to other materials can lead to a fast spectrum reactor, the neutrons are absorbed to cause a fission before slowing down.

The nuclear control system interacts with the basic nuclear system to provide control of the chain reaction and set the reactor power level. Important elements are: Instruments such as sensing elements (ion chamber, fission chamber) and circuitry to indicate the intensity of the chain reaction. An auxiliary neu-

tron source to be inserted in the reactor at low power levels so that the instruments may always have a detectible level of neutrons and monitor low-power operation. Neutron control elements (control rods) that are inserted in the core or reflector and actually control the neutron by absorption or multiplication. Mechanical linkages and servo systems that move the control elements on human or automatic command.

The heat removal system consists of coolant flow passages inside the core and appropriate external pumps and piping. An ultimate heat dump to the atmosphere or a river must be provided.

The reactor structure consists of the basic mechanical support to keep the various components in proper position. For example, a portion of a fuel element is usually present for structural reasons.

The shielding and containment components have been mentioned previously.

(*b*) Complexity: From the brief description above, it may not be obvious that nuclear reactors are complex. In general, except for very simple critical assemblies, nuclear reactor installations are large, complex facilities requiring considerable engineering management and coordination in their design and construction, and good administrative management in their operation.

Even if all the basic problems are understood (and there still remain some unknowns), this complexity makes it very difficult to predict the detailed behavior of such a machine from first principles. Seemingly unimportant features can be overlooked, and can be of practical significance.

Currently, with the rapid strides in reactor development which are underway in the United States, not only are individual reactors complex but also the whole picture of reactor technology is changing extremely rapidly as many novel types of machines are investigated and put into development (reference 1).

(*c*) Reactor control:

(1) Delayed neutrons: A brief description of the elements of a nuclear reactor control system has been given. The feasibility of practical reactor control lies in the fact that some of the neutrons emitted in the fission reaction are emitted after some delay from the decay chains of the fission fragments.

Within a nuclear reactor neutrons are being repeatedly produced and absorbed. The time between the birth and death of a neutron is called the neutron lifetime (or neutron generation time). This time is quite short, one millisecond for a large graphite moderated thermal reactor to as short as one tenth of one microsecond for a fast neutron spectrum reactor. The quantity, k, the multiplication of the reactor, is defined to be the ratio of the average number of neutrons in a given generation to the average number in the preceeding generation. The following definitions are usual:

If:

(1) $k>1$, the reactor is supercritical, the neutron level and power level are increasing.

(2) $k=1$, the reactor is critical, the neutron level and power level are constant.

(3) $k<1$, the reactor is subcritical, the neutron level and power level are decreasing.

Now k works on each new generation of neutrons, and acts like compounding interest. Consider a supercritical reactor assuming no delayed neutrons and with $k=1.02$. The neutron level (and power level) will double in 35 generations or (with one millisecond generation time) at the end of 0.035 second! With $k=1.005$, the time to double the power is 0.14 second.

We now consider the delayed neutrons. In the case of U–235 of all neutrons produced in fission, a fraction 0.0073 are produced with an average delay of 10 seconds. As long as (k—1) is less than the delayed fraction the reactor acts as if the neutron generation time were several seconds rather than the 0.001 second of the preceeding example. Detailed calculations give the table:

k	Time to double power [1]	
	No delayed neutrons	Fraction delayed neutrons is 0.0073
1.005	0.14 second	2.1 seconds.
1.020	0.035 second	0.054 second.

[1] Neutron generation time 0.001 second.

This is an example of a general result: as long as $k-1$ is less than the fraction of delayed neutrons, the reactor power level changes over periods of seconds to minutes and the reactor is easy to control. If $k-1$ appreciably exceeds the delay fraction (0.0073), the reactor changes power quite rapidly. The control of all reactors exploits this fact, and their planned operation keeps the excess reactivity, $k-1$, less than the delayed fraction of neutrons. It is entirely practical to design reactors and control systems to do this, although variations due to fuel burnup and reactor temperature changes may require as much as 0.30 excess reactivity in the basic nuclear system which is "held down" by control rods.

As long as the excess reactivity is well within the fraction of delayed neutrons (sometimes called a dollar and indicated by $), the time behavior of the reactor is determined by the delayed neutron periods (seconds to minutes) and a fast spectrum reactor is as readily controlled as a thermal spectrum reactor despite the much shorter fast spectrum nutron generation time. With a fast reactor care must be taken not to exceed the delayed fraction.

(ii) Reactivity effects: In many reactors it turns out that the reactivity, or value of $k-1$, is changed when the reactor temperature is changed. Since a reactor produces heat, it can change its own temperature.

If increasing temperature increases the reactivity, this can lead to higher power levels, more heating, and the reactor can boot-strap itself into a nuclear excursion. Such a reactor is said to have a positive reactivity coefficient, to be unstable, and is called autocatalytic. Such machines are dangerous and should be avoided.

If increasing temperature decreases the reactivity, it is said to have a negative reactivity coefficient and is usually called a stable reactor.

For either positive or negative reactivity cofficient there may be a time delay of several seconds or more between a change in power and an effect on k. (For example, the time to conduct heat from a fuel element into a moderator which changes the behavior of thermal neutrons). This delay may allow feedback and divergent reactor power level oscillation even when the cofficient is negative. The oscillations take some time to build up, and there is usually ample time to shut the reactor down if this occurs (reference 2). Nevertheless, even this should be avoided whenever possible.

(iii) Built-in control: At sometime, practically everyone makes mistakes. for this reason, it is usually considered very desirable to have negative, quick-acting, reactivity coefficients. Then if a mistake is made in manipulating the controls (as in wiring-up the control system if it is automatic), the reactor itself will control itself. This intrinsic, built-in, stability appears to be attainable for many reactors and is a continuing goal of reactor design.

2. The Nature of Nuclear Reactor Hazards.—The hazard of a nuclear reactor is due to the possibility of release of the large quantity of radioactive material contained within it.[1] The bulk of this radioactivity is due to fission products although some is due to neutron activation and the nuclear fuels.

If substantial quantities of radioactivity escape, we know from the Brookhaven report that this can be a very serious matter (reference 3). The essential point is to prevent an escape of radioactivity.

Nuclear reactors cannot explode like an atomic bomb, or produce a nuclear explosion as violent as chemical explosives.[2] This is true for even fast reactors (reference 4). There is no explosive danger to off-site people (the public).

If material does escape from the reactor, the major radioactivity and major hazard is due to fission products. They constitute many different chemical species, and this makes cleanup and decontamination difficult since no single procedure will get them all.

This hazard is real; in its worst form it can be serious indeed (reference 3), and it should not be ignored. However, I feel sure that if proper attention is given to the problem, particularly the technological aspects of safe reactors, that controlled fission reactors can very rapidly supply increasing material benefits to mankind. In this connection, the Division of Reactor Development of the Atomic Energy Commission has an effective and expanding program of research underway directed to the technological aspects of reactor hazards (reference 5).

---

[1] By employing liquid fuel, and by continuous chemical processing during reactor operation, this large accumulation of radioactivity can be almost eliminated. This is an attractive safety feature of the liquid homogenous reactor.

[2] For certain kinds of reactors, if they should get out of control and melt, there is a possibility of chemical explosion from reacting core components. Aluminum fuel plates in water coolant-moderator are an example. If the plates were to melt (due to a nuclear excursion) an explosive aluminum water reactor could theoretically occur. Whether it will really occur, and occur rapidly, in a nuclear reactor is not clearly settled. More experimental work is needed to clarify this problem. Even so, there is no off-site explosive hazard.

The hazard of a nuclear reactor can be thought of as the product of two factors: the consequences of a radioactivity release, and the chance that such a release might occur. Both are discussed in the Brookhaven report (reference 3). The chance of a release is not known on the basis of experimental statistics (of the kind obtained by insurance companies on human life expectancy). Fortunately, no serious releases of radioactivity from a nuclear reactor have occurred so there are no statistics. I hope such statistics will not be forthcoming.

As pointed out in Section 1: The Nature of Fission Chain Reactors, reactor technology is undergoing rapid growth in the number of reactors, in the variety of reactor types, in the number of novel kinds being investigated, and in the number and variety of new organizations undertaking reactor activities. Furthermore, reactors are complex machines. Consequently, the ultimate responsibility for reactor safety will have to rest with the organizations that design, build, and operate nuclear reactors. However, systematic review by a skilled body of experts can help such organizations to achieve adequate coverage of hazard problems.

3. Technical aspects of hazards.—The following description is not exhaustive but illustrative. It is frequently helpful in organizing hazard considerations. Often some particular reactor will exhibit some specific characteristics which require careful attention, but which are not included in the following summary.

Nuclear reactors may break open and release fission products by undergoing (1) a runaway nuclear excursion (as runaway nuclear oscillation, (2) by meltdown due to radioactive decay of the accumulated fission products if adequate cooling of the reactor is not maintained (this can happen even if the neutron chain reaction and the associated fissions are stopped), and by (3) possible chemical reactions between the core components.

The possibility of runaway, and desirable reactor stability features were mentioned in the section 1 (*c*) Reactor control.

Cooling failure may occur due to failure in the external cooling system (pipe failure, loss of pumping power) as due to plugging of flow passages in the core (perhaps due to melting brought about by a nuclear runaway). The inability to completely "shut-off" heat generation poses a difficult problem. Continuous fission product removal requires liquid fuel, or emergency, standby, cooling systems are ways to mitigate this problem.

Chemical reaction, clearly not present under normal conditions, may take place if the core is melted either by cooling failure or by a nuclear runaway.

More conventional sources of disruptive energy, possibilities which also require care, are: Steam explosion in boiling water or pressurized water reactors, sodium fire with liquid metal cooled reactors, combustion of organic moderators, or burning of air-cooled graphite piles.

4. Reactor types.—The power level, and therefore the quantity of fission products, usually progresses with reactor types from extremely large for power and production reactors, to large for research and test reactors, to substantial for reactor experiments, to negligible for critical experiments. Fortunately, the chance of a radioactive release would appear to run the other way. The power and production reactors are run on steady routine schedules, the large research reactors are nearly the same in this regard, the "reactor experiment" reactors are less known and less routinely operated, and the critical experiments are flexible (variable in geometry and nuclear characteristics). The only nuclear runaway accidents of any moment have occurred with critical experiments or with reactor experiment reactors.

At startup, a brand new nuclear reactor has not accumulated radioactivity. Although the startup procedure is more risky than regular operation because the precise calibration of the reactor is not established (the startup procedure supplies this precise calibration, the absence of accumulated radioactivity minimizes the risk and makes public hazard almost negligible.

5. Radioactive waste.—Radioactive waste materials from reactor operation present a problem requiring care and good management. They do not represent an acute hazard problem like that of a malfunctioning reactor.

B. Controlled thermonuclear reactors.—The hazards that may eventually be encountered from controlled thermonuclear reactors are very difficult to anticipate, may turn up in a totally unexpected quarter, and may well turn out to be negligible. With the understanding that what follows is "crystal gazing," I will attempt to answer the questions suggested by the outline.

1. Radioactive hazard: The nuclear fuels for thermonuclear system are not radioactive, with the exception of tritium (Post, reference 6, suggests D, T, He-3,

Li-6, Li-7). Tritium is no hazard outside the body. The fission fuels are hazardous with Pu-239 and U-233 having much more stringent limits than tritium in the body.

Perhaps the best test is delayed, activated, and produced, activity associated with the reactions. Assume for example:

For the fission reaction

$n+U-235 \rightarrow f.f.+2.5\ n$ (2 Mev., each)

For the thermonuclear reaction we add up the first three given by Post (reference 6):

$D+D \rightarrow He^3+n$ (2 Mev.)
$D+D \rightarrow T+p$
$D+T \rightarrow He^4+n$ (14 Mev.)

$5D \rightarrow He^3+He^4+p+n$ (2 Mev.) $+n$ (14 Mev.)

Assuming arbitrarily that:

(1) 2 Mev. neutrons do some activation in fission and fusion.
(2) 14 Mev. neutrons to 3 times the activation as 2 Mev. neutrons.
(3) Half the activity is prompt and half is delayed.
(4) The 2.5 x 2 Mev. neutron activation is 6 Mev. prompt and 6 Mev. delayed.

For the fission system the assumptions (3) and (4) are reasonable but arbitrary. They may be meaningless for fusion. For example, fusion systems may be designed to eliminate activation effects.

With these assumptions one can make the table:

	Fission	Thermonuclear
Immediate energy:	*Mev*	*Mev*
Direct	178	25
Activation	6	9
Delayed energy:		
Direct	13	
Activation	6	9
Total energy	203	43
Ratio: Delayed/total	0.093	0.21

This implies that the delayed energy (accumulated radioactivity) could be about twice as bad for thermonuclear as for fission. However, some two-thirds of the fission reaction accumulation is fission products which are essential for the machines' operation. The thermonuclear machine could be designed for minimum activation if necessary.

2. Other hazards: Without a design, speculation is very unreliable.

3. Future energy demands: The supplies of deuterium in the world (oceans), in terms of energy, represent an inexhaustible supply of power compared to present consumption (about 10 billion years).

4. Time scale for thermonuclear development: This prediction is difficult, and I will assume that economic fusion power is of interest. One may argue as follows:

(1) Currently fusion has not reached the development of the late 1942 Chicago fission pile (14 years or more behind fission).

(2) Fission is not yet economic, but may be so by 1970 (W. K. Davis, private communication) (12 years).

(3) Fusion development seems harder than fission development (5 years).

(4) Fossil fuel shortage will be eased by fission reactors by the time fusion of practical interest so that the economic pressure for fusion development will be reduced (5 years).

If all this is added together:

Practical economic fusion not before the 1990's. It is possible, but unlikely, that this could move up to the 1980's with remarkable luck.

Representative HOLIFIELD. The committee will stand adjourned until 2 o'clock when we will have Dr. Graves and the people from the Department of Defense before us.

(Whereupon, at 12:30 p. m., the committee recessed, to reconvene at 2 p. m., of the same day.)

AFTERNOON SESSION

Representative HOLIFIELD. The committee will be in order. It is our intention this afternoon to have testimony on the production of radiation and radioactivity by the detonating of nuclear weapons.

Our first witness on this subject is Dr. Alvin C. Graves, of the Los Alamos Laboratory. Dr. Graves, this committee is pleased to have you before us again. You have been before us many times over the past 10 or 11 years, and I know of no one that is better qualified to give us testimony on this subject than you, because you have had charge in a great many instances of these weapons tests.

So at this time, sir, the committee would be glad to hear your testimony.

STATEMENT OF DR. ALVIN C. GRAVES, LOS ALAMOS SCIENTIFIC LABORATORY [3]

Dr. GRAVES. Mr. Chairman, we are teachers at heart and are used to talking at the blackboard. So if you will pardon me, I will feel much more at home if I can talk at the board.

I would also like very much to express my regret to you that I was unable to prepare a written statement for you in time to be submitted for the record beforehand. On the other hand, I do have a written record here now, and if I may leave this with you, you can make such disposition of it as seems appropriate to you.

Representative HOLIFIELD. Thank you.

Dr. GRAVES. In this, the fifth topic of the hearings before your committee, you have asked me to cover the production of radiation and radioactive materials by nuclear-weapon detonations.

Although Dr. Mills in his discussion this morning went into the fission and fusion processes to some extent, I would like to go over some of the material that he covered, because the production of radia-

tion and radioactive material is in this set of processes and, unless we cover them carefully, we will not be able to make the production of radiation understandable.

Moreover, in view of the desire to have this hearing not only for our own purposes but for purposes of informing the public, I hope you will bear with me if I speak to some extent on material which is well known to you.

Representative HOLIFIELD. Would you like to have the prepared testimony put in as you have prepared it, Doctor Graves?

Dr. GRAVES. If you would.

Representative HOLIFIELD. It will be accepted on that basis.

(The statement referred to follows:)

THE PRODUCTION OF RADIATION AND RADIOACTIVITY BY DETONATING NUCLEAR WEAPONS

(By Alvin C. Graves)

In this, the fifth section of the hearings before your committee, you have asked me to cover the production of radiation and radioactive materials by nuclear-weapons detonations. Although earlier witnesses have presented you with general background material on atomic radiation and its effect, I feel it appropriate to risk some repetition in my discussion since the origin of radiation and radioactive materials in detonations is in the fission process and in reactions with neutrons produced in the detonation. In view of your desire to use this investigation to inform the public on the subject of fallout from nuclear-weapons tests, I should like to request your indulgence if I speak to some extent on material which is already well known to you.

1. Description of nuclear-weapon detonation

Nuclear weapons differ from normal high-explosive bombs in three important respects. In the first place, their energy may be made orders of magnitude greater; second, their detonation is accompanied by intense thermal and nuclear radiation; and, third, there remains when the detonation is completed extremely large amounts of radioactivity. In describing the detonation of an atomic weapon completely, one should discuss in great detail blast effects, which differ in some important ways from blast effects of normal explosions, thermal radiation, and light which, as mentioned above, are novel features of nuclear detonations, initial nuclear radiations consisting of gamma, neutron, alpha, and beta radiations and, finally, delayed radiations. However, for purposes of this hearing, I propose to place my major emphasis on the last two of the above topics.

The release of energy in nuclear detonations deposits a very large amount of energy in a very small region of space in an extremely short time. For example, the complete fission of 1 pound of uranium (a little over a cubic inch) would produce an amount of energy equivalent to 9,000 tons of TNT, and the fusion of a pound of deuterium would produce energy equivalent to 26,000 tons of high explosive. Hence, the initial effect is a rise of temperature of bomb materials to a very high temperature of many million degrees as contrasted with perhaps 5,000 degrees in the case of ordinary high explosives. This extremely high temperature, not very different from that at the center of the sun, is accompanied by tremendous pressures such that, at a very few microseconds, pressures of the order of millions of pounds per square inch exist, and an expansion of vaporized bomb materials begins to take place. At 0.7 millisecond, the fireball for a 1-megaton detonation will have a radius of 220 feet, and at about 10 seconds will have reached its maximum diameter of about 7,000 feet. This growth in size is accompanied by a decrease in temperature and pressure, formation of a shock wave which produces the familiar blast effects and, at the same time, the fireball begins to rise and to engulf large quantities of surrounding materials, air, dirt, or water, depending on the particular situation in which the bomb was detonated. While the ball of fire is still luminous, fission products, fissionable material, bomb casing, and other materials will be present in the form of vapor, whereas, as the fireball increases in size and cools, these vapors will condense and be absorbed in or on other particles such that the cloud becomes a mixture of gaseous and solid radioactive particles. The cloud from a weapon in the megaton range would rise initially at a rate like 250 miles per

hour and, after a minute, would have risen perhaps 4 miles or more. It is the extremely rapid rise of fireball which makes meaningful a distinction between immediate or prompt radiation and delayed or residual radiation. The amount of radiation which can reach a point from distances like 4 miles is small and, hence, establishing an arbitrary division by defining all radiation delivered in the first minute as prompt radiation and all after 1 minute as residual radiation tends to correspond to a distinction between that radiation which is delivered from the fireball and that which is delivered from fallout, or from deposited or induced radioactive materials. Because of its connection with the problem of radiation, the following table is given as an illustration of the rise of a cloud from a 1-megaton detonation.

Rate of rise of cloud from 1-megaton detonation

Height (miles)	Time (minutes)	Rate of rise (miles per hour)
2	0.3	300
4	0.75	200
6	1.4	140
10	3.8	90
14	6.3	35

With different detonation yields and atmospheric conditions, different times and rates of rise would, of course, be observed.

2a. The fission process

For our purposes, an atom may be represented as composed of a massive central nucleus and a number of relatively light electrons rotating about it. The revolving electrons are important in ordinary chemical reactions, but in nuclear reactions it is the nucleus which is of importance. In most reactions in which a neutron is involved, the resulting nucleus will have nearly the same mass as the original nucleus and, hence, the number of possible product nuclei is very small. In the fission process, where the fissioning nucleus splits into two unequal pieces, both of which are very different in mass from that of the original atom, the number of possible product nuclei is very large indeed. It seems, for example, that U–235 may be split in something like 40 different ways, and that over 200 different nuclides, counting primary fission fragments and decay products, may be formed. Since these products are highly radioactive, for reasons that I will discuss, the resulting radioactivity is that of a mixture of many radioactive nuclei with different periods and different modes of disintegration.

The simplest atomic nucleus is that of hydrogen, which has an atomic mass of 1, contains 1 unit of electrical charge, and is known as the proton. All other atomic nuclei contain a number of protons and neutrons. The neutron also has an atomic mass of 1, but has no electrical charge. Hence, a neutron can be converted to a proton by loss of an electron. In nature there appears to be a strong tendency for the number of neutrons and protons in nuclei to be equal. For example, the helium nucleus contains 2 neutrons and 2 protons. The nucleus of 1 species of lithium contains 3 neutrons and 3 protons; boron, 5 neutrons and 5 protons; carbon, 6 and 6; nitrogen, 7 and 7; oxygen, 8 and 8; and so forth. Hence, uranium, with its 92 protons and 143 neutrons, is very neutron rich, and fragments resulting from fission are unstable such that, to become stable, they must either lose neutrons or convert neutrons into protons. Both processes occur. A number like 2, 3, or 4 neutrons is emitted, essentially instantaneously. And then, at various times from a small fraction of a second to many years, a nuclear neutron is converted into a nuclear proton by the emission of an electron. A fraction of 1 percent of emitted neutrons are delayed. That is, although about 99¼ percent of neutrons will be emitted within about 10 to 12 seconds of fission, ¾ percent will be emitted at times as long as several minutes. Periods for delayed neutrons vary from a fraction of a second to almost a minute.

Reference to the fission yield curve of U–235 indicates that production of masses 95 and 139 should be a common mode of fission of that element. A reasonable distribution of uranium protons suggests that these fragments might be Sr–95 and Xe–139. These fragments would both be unstable and would decay by the following processes:

$$Sr^{95} \rightarrow Y^{95} \rightarrow Zr^{95} \rightarrow Cb^{95} \rightarrow Mo^{95} + 4e^- + \text{gamma rays}$$
$$Xe^{139} \rightarrow Cs^{139} \rightarrow Ba^{139} \rightarrow La^{139} + 3e^- + \text{gamma rays}$$

Hence, in that particular mode of fission, 4 radioactive decays would occur in the light element and 3 in the heavy, with the emission of 7 electrons with 7 different decay periods, and with the production of many gamma rays of many energies. In fission with slow neutrons, production of stable fission fragments appears to be rare, although short chains of 1 or 2 decay stages appear. Two of the longest known are $Kr^{97} \rightarrow Mo^{97}$ among lighter fission products, and $Xe^{143} \rightarrow Nd^{143}$ among heavier. Each chain involves 6 stages of decay. The average is about 3 stages, or slightly more. During most such processes, gamma rays of various energies are emitted. These phenomena, involving the conversion of one element into another with emission of gamma rays and electrons, are the cause of much of the radioactivity observed in fallout. Induced activity will be discussed in a later section.

2b. Fusion process

The fusion process is quite different from the above and, hence, has a different importance in radiation and fallout considerations. Among light elements, binding energy per nuclear particle tends to decrease with increasing mass as contrasted with an increase with increasing mass in heavy elements. Hence, among light elements energy is released when light elements are joined together to make heavy elements. Such reactions, because of this process of joining atoms together, are called fusion reactions and, because they can be initiated and sustained by high temperatures, are also known as thermonuclear reactions. The number of modes is always extremely limited, at least for low energies and low mass numbers, as contrasted with the large number of modes in fission. Two atoms of deuterium, for example, can fuse in two ways; one involves production of hydrogen of mass 3 or tritium and a proton; the second involves production of helium of mass 3 and a neutron. In this case, only tritium is radioactive. Moreover, tritium itself has a very high probability of fusing with deuterium so that, under many conditions, tritium will combine with deuterium to produce helium of mass 4 and a neutron. In deuterium fusion, the following reactions might occur:

$$_1H^2+{}_1H^2 \rightarrow {}_2He^3+{}_0n^1+3.2 \text{ Mev}$$
$$_1H^2+{}_1H^2 \rightarrow {}_1H^3+{}_1H^1+4 \text{ Mev}$$
$$_1H^2+{}_1H^3 \rightarrow {}_2He^4+{}_0n^1+17 \text{ Mev}$$
$$_2He^3+{}_2He^3 \rightarrow {}_2He^4+2{}_0n^1+11 \text{ Mev}$$

Hence, the net direct result of fusing deuterium nuclei is production of protons, alpha particles, and many neutrons, but essentially no radioactive particles.

2c. Induced activities

A secondary source of radioactive materials results from neutrons produced in both fission and fusion processes. It was mentioned above that, depending on the particular mode of fission, two or more neutrons may be emitted and that deuterium fusion is accompanied by production of many neutrons. In any detonation of a nuclear weapon, some of these neutrons will escape and react with nitrogen atoms in air to form carbon 14 which is radioactive. In case detonations occur under conditions such that dirt is exposed to neutrons, many other neutron reactions can occur. Normally, radioactive materials induced by such processes have relatively short lives and will not be of major importance. Carbon 14, however, has a long life of over 5,000 years. Since it emits no gamma rays and only relatively weak beta rays, and since the amount formed will not be large compared to that that is present in nature, it will not be a significant activity. Oxygen absorbs fast neutrons to some extent, but the isotope of nitrogen formed has a half-life of only 7 seconds and, after a few minutes, will have completely decayed.

An important contribution to residual activity will be due to 14.8-hour sodium 24 formed by neutron capture by sodium. It emits beta particles and two relatively high energy gammas of 1.4 and 2.8 Mev. 2.6-hour Mn–56 emits beta particles and several high energy gammas. With some soils this element might cause an appreciable activity for a few hours, but within a day its activity would have been reduced to less than a percent of its initial amount. Si–31, with a half-life of 2.6 hours, is formed in appreciable quantities but is chiefly a beta emitter. Al–28 has a half-life of only a few minutes and, hence, will have disappeared in the first hour. The chlorine present in salt produces 37-minute Cl–38 which emits betas and high energy gammas.

Other materials such as zinc, copper, iron, glass, and salt in foodstuffs might, under some conditions, become active enough to be significant. Normally, how-

ever, induced activities will have a short half-life and make a significant contribution for only a relatively short time or will have little energy to emit.

2d. Initial radiation

As stated earlier, initial nuclear radiation is defined as that radiation which is delivered during the first minute after a detonation. Although initial neutrons and gamma rays constitute only about 3 percent of bomb energy as compared with 33 percent appearing as thermal radiation, a considerable proportion of bomb casualties can be caused by initial nuclear radiations. Fifty percent of people shielded by as much as about 2 feet of concrete would be killed by initial gammas and neutrons 1 mile from a 1-megaton bomb. A much lighter shield would give complete protection from thermal radiation.

Initial radiation consists of almost all neutrons, a part of gamma radiation, some beta and alpha rays. Alpha particles come from two sources. They are emitted from fissionable materials, plutonium and various isotopes of uranium, or from thermonuclear or other reactions in which alpha particle emission takes place. Beta particles come from fission fragment decay, as well as from such processes as photoelectric and Compton effects. Alpha particles, besides being relatively rare, have a short range like an inch or so in air and, hence, are not important in initial radiation. Beta particles have somewhat greater range but still cannot reach the ground from an air-burst. Both neutrons and gammas penetrate air to considerable distances and both are highly injurious to living organisms. Hence, they constitute by far the most important part of initial radiation. To a great extent, neutrons are slowed down and captured in bomb materials themselves, but enough fast neutrons escape to constitute an appreciable hazard at considerable distances. Only about a percent of gamma rays produced directly in fission escape from the immediate region. However, this contribution and that of gamma rays produced in other processes, as discussed below, produce sufficient intensity at considerable distances to constitute a real hazard. Gamma rays present in initial radiation come from a number of different sources. They originate not only in fission but also in various other neutron reactions. First, neutrons may be captured with formation of a highly excited compound nucleus which may lose its excitation by emission of gamma rays. For example, when neutrons are captured by nitrogen to form C–14, two high energy gamma rays are emitted. These can be an important component of initial radiation. Second, neutrons may also react with nuclei with the emission of protons or alpha particles, and gamma rays are frequently emitted in such processes. And, finally, neutrons may be scattered inelastically by nuclei with the emission of gamma rays. That is, a fast neutron in a collision with a nucleus may transmit some of its energy to that nucleus leaving it in an excited state. The excited nucleus may then revert to its normal state by emission of a gamma ray.

Fission fragments themselves decay with periods from a millionth of a second or less to many years, and many of these decays during the first minute are accompanied by emission of gamma rays known as delayed gammas. Although instantaneous and delayed gammas contributing to initial gamma radiation are produced in about equal amounts, instantaneous gammas are absorbed so strongly that they constitute only about 1 percent of external dose.

Gamma rays lose energy or are absorbed in going through matter, by excitation and ionization. It is believed that the chemical decomposition of molecules caused by this effect is the major cause of injury to animals and plants. Therefore, quantity of gamma radiation or gamma ray dose is defined in terms of ionization produced. The dose-distance relationships for gamma rays and neutrons are exceedingly complicated because of the large number of effects involved, but rough analytical expression can be obtained. Since surface area of a sphere increases with square of radius, intensity—that is, gamma rays (or neutrons) per square centimeter—will decrease with square of distance. In addition, since gamma rays and neutrons are strongly absorbed, degraded in energy, and scattered in air and other materials, there will be an exponential decrease depending on the absorption properties of air and these materials. Due to a balance between various effects, gamma ray dose at a given distance is roughly proportional to the yield up to about 80 or so kilotons. But, above that, the dose increases sharply with yield such that at 100 kilotons the dose will be 50 percent higher than indicated by a direct proportion, and at a megaton will be high by about a factor of five. This increase is due to decreased air density because of long negative pressure phase associated with large yields, and is partly counterbalanced by increased dose at lower yields caused by slower cloud rise with con-

sequent increase in contribution from fission product gamma rays. The net effect is very complicated, but roughly gamma ray dose decreases by a factor of 10 every 780 yards, in addition to inversely as the square of distance, and neutron dose decreases by a factor of 10 every 560 yards. Appropriate consideration of all the above factors indicates that dose-distance relationship for gamma rays can be approximated roughly by the following formula:

$$N=\frac{8.4\times10^{8}W}{D^{2}}e^{-D/342}\text{ rems}$$

where W′ is yield in kilotons increased at yields of 100 kilotons or above, as indicated previously, and D is distance in yards.

Neutron dose-distance relationship may be expressed to a very poor degree of approximation by the following formula:

$$I=1.4\times10^{8}\frac{W}{D^{2}}e^{-D/238}\text{ roentgens}$$

This ignores variations because of variation in neutron capture in bomb materials for different designs, as well as differences because of high energy neutrons from fusion reactions, and so on.

2e. Residual radiation

About 0.11 pound of fission products are produced for each kiloton of fission energy yield and its radioactivity at one minute would be comparable with that of many pounds of radium. A megaton of fission energy would, therefore, result in activity at one minute comparable with that of very many tons of radium. During the first 24 hours there would be a decrease by a factor of more than 6,000, but it has been estimated that this activity, if uniformly spread over 10,000 square miles, would cause a radiation intensity after 24 hours of 2.7 roentgens per hour at a distance of 3 feet above the ground. Unprotected personnel in that area would receive more than 300 R after the first day. During the first day they would receive many times that amount. Of course, activity would not be spread uniformly over such an area. Actual fallout situations will be covered by later speakers.

An indication of the speed with which fission product activity decreases can be obtained by the rough rule that for every sevenfold increase in time there will be a tenfold decrease in activity. For example, after 7 hours the activity would be one-tenth of its value at 1 hour; after 49 hours, or about 2 days, it would be 1 percent of its value at 1 hour; and after about 2 weeks, it would be one-tenth of a percent of its value at 1 hour.

There is given below the estimated total gamma activity of fission products from a 20-kiloton atomic bomb, expressed in megacuries, at various times after the detonation.

Total gamma activity of fission products in megacuries

Time:	*Activity*	Time—Continued	*Activity*
1 minute	820, 000	1 month	2. 3
1 hour	6, 000	1 year	. 11
1 day	133	10 years	. 008
1 week	13	100 years	. 0006

3. Partition of energy from detonations

The partition of energy from a nuclear explosion as betwen blast and shock, thermal radiation, and nuclear radiation varies appreciably with device design and with condition of firing. As a general approximation, nevertheless, I shall give the division which could be expected from detonation of a device of 1-megaton yield, fired within the earth's atmosphere, but at such an altitude that comparatively little extraneous material would be available to be made radioactive by escaping neutrons (as for example, if fired at an altitude of a few thousand feet above the earth). To some extent such a partition is meaningless since eventually all forms of energy will be converted to heat. However, initially energy is partitioned about as follows. About half the energy would be released as blast or shock, one-third would occur as thermal radiation (heat or light), and some 15 percent would be in the form of nuclear radiation. Of this 15 percent roughly one-third would be initial radiation occurring within

1 minute after firing, while two-thirds would be residual radiation. Some residual radioactivity can be deteced for many years after detonation.

The blast or shock energy would have effects quite similar to those experienced in case of ordinary high explosive detonations. These would consist of an initial shock front (the first arrival of highly compressed air), a later region of high and low pressures behind the shock front, and a violent wind flow. The latter would initially be directed in an outward direction, but later in a reverse direction. In the case of a typical air burst, the distance at which a given overpressure occurs varies generally as the cube root of yield. The term "generally" is used since effects such as reflection and refraction of shock waves, dust loading, and the like, may increase or decrease pressures and materially change blast effects at a given point. As an indication of the order cf magnitude of the effect one might expect from blast phenomena, the burst of a 20-kiloton weapon at an altitude of several hundred feet would destroy beyond economical repair multistory reinforced concrete buildings at distances up to a half mile. A 1-megaton burst fired under comparable conditions would cause similar damage at distances up to 2 miles.

The one-third of weapon energy emerging in the form of thermal radiation is contained initially in a relatively small voume of air and incandescent gases resulting from vaporization of device components. This intensely hot spherical mass termed "fireball' is visible until thermal energy has been dissipated and temperature reduced to such an extent that visible light is no longer emitted. The initial fireball temperature is of the order of several million degrees and thermal radiation is made up of rays in the ultraviolet, visible, and infrared. As the fireball cools there is a shift to long wavelengths, but phenomena are complicated by absorption in outer portions of the fireball and in shocked air, by change from emission to absorption spectra, and by changes in position and chemical composition of materials involved. The extent of injury or damage to a person or material from thermal radiation is a function of total energy and of time duration of pulse received. From a given weapon, or from weapons of comparable yield, quantity of thermal radiation energy received per unit area is primarily a function of distance from burst. The amount decreases inversely as distance squared and exponentially because of attenuation in the atmosphere. The period over which thermal energy is given off from an explosion increases with yield—that from a kiloton device being limited to a few tenths of a second but, for a megaton device, the period may extend to several seconds. A 20-kiloton burst could be expected to ignite combustible materials at ranges up to 2 miles, while a 1-megaton burst could have similar effect up to 10 miles. The 20-kiloton burst could cause first degree burns to exposed skin surfaces at ranges of 3 miles, while a megaton burst could cause similar burns at 14 miles.

The partition of energy between various nuclear radiations as observed at a distance depends materially on device design and cannot be discussed in detail in unclassified language. It should be sufficient to point out that neutrons are efficiently converted to gamma rays in heavy materials, gamma rays are absorbed and converted to thermal energy in heavy materials, and neutron energy spectrum depends materially on whether, or on the way in which, fusion reactions are employed, and on the kind and amount of heavy materials used.

4. Types of burst and effect on fallout

For descriptive purposes, three types of burst can be distinguished. These are air, surface, and subsurface bursts. A high air burst is one in which the hot fireball does not touch the earth and, for a megaton device, is about 3,000 feet high or more.

Initial nuclear radiations are absorbed and scattered less in low density air associated with air bursts. Hence, there is less energy degradation and mean free paths are longer. Additionally, less dirt is stirred up to further absorb and scatter radiation. The result is that dose at a given distance is greater.

In the event of high air bursts, fission products are widely dispersed and very little is deposited on the ground under or near the point of detonation. This is the safest type of burst from the point of view of nearby regions as far as fallout is concerned. However, this puts the maximum amount of activity into the atmosphere and is the worst type as far as worldwide fallout is concerned. As height of burst is decreased toward the earth's surface, more and more dirt is mixed with the cloud and more of the activity is absorbed on larger, more massive particles and, hence, falls out locally.

In the case of subsurface bursts, much initial radiation is absorbed within a short distance of the explosion and dissipated in heating ground or water or, in the case of neutrons, in producing induced activities. As depth of detonation increases, less activity appears in the atmosphere and more is deposited locally. Under such conditions, the maximum local fallout and minimum worldwide fallout occurs. At sufficient depths, the detonation would be entirely contained and no fallout problem would exist. Ground water contamination concentration would be a maximum for the latter case and a minimum for high air bursts. Subsurface bursts under water have extreme contaminating effects, and effects on marine life and contamination of seafood can be serious.

5. Limitation on data

Although initially residual radiation decreases approximately as t–1.2, departures from the law becomes appreciable after the first half year or so. Better data on dose and gamma ray energy as a function of time is desirable.

In estimating dose to people one needs knowledge of shielding of typical structures and data for calculating probable dose reduction to individuals engaged in typical activities.

After long time intervals, when most activities will have decayed to such an extent as to be negligible, the activity remaining will largely consist of Cs–137 and Sr–90. More data is needed on uptake of these materials in plants, their conversion to food, and effect on biological systems.

In order adequately to discuss residual radiation for typical situations, much more data is needed as to particle size versus height in the cloud as a function of type of burst, and activity per particle as a function of particle size and position of particle.

Although much effort has been expended on determination of patterns of deposition of residual radioactivity, existing data leaves much to be desired, especially for large yields.

6. Recommendations

It is recommended that:

1. Additional effort be allocated to obtain data as indicated above.
2. Since the actions of individuals within seconds after a detonation could make a difference of thousands of fatalities and could decrease the seriousness of many casualties, it is recommended that increased effort be expended in informing the American people of the effects of weapons and in establishing personal civil defense.

Dr. Graves. I would like to give you a general description of a nuclear-weapon detonation.

Nuclear weapons differ from normal weapons in three important respects. In the first place, the energy from nuclear weapons can be many orders of magnitude greater. The President has spoken about fission weapons of the order of 100 times greater than ordinary weapons. He has spoken about thermonuclear weapons in the millions of tons. So we can speak about nuclear weapons having yields equivalent to millions of tons of high explosive without getting into a classified area at all.

In the second place, when a nuclear weapon detonates, its detonation is accompanied by a very large amount of radiation.

In the third place, when a detonation is over, a considerable amount of residual radioactivity remains on the ground in the neighborhood of the detonation.

In describing such a detonation completely, one should therefore discuss first of all a blast or shock wave. Then one should discuss the thermal radiation, heat, and light which are given out at the time of the detonation. One should then go on to discuss the radiation that proceeds from the detonation, and finally discuss the residual contamination which is left on the ground.

Because of the purposes of this hearing, I intend largely to restrict my comments to the latter two of these subjects.

The release of energy in a nuclear detonation deposits a very large amount of energy in an extremely small region of space. One kiloton—1,000 tons of high explosives—produces a certain amount of energy. That same amount of energy could be given out by the fission of something like a cubic inch of uranium which is about a pound.

So we have a tremendous amount of energy in a real small region of space.

Similarly, in the fusion reaction, the fusion of 1 pound of deuterium could produce an amount of energy equal to that of about 26,000 tons of high explosive. Hence, the initial effect of such a detonation is the rise of temperature of the materials themselves to a very high figure—many millions of degrees—whereas in a normal high explosive detonation, the corresponding temperatures are of the order of 5,000°. Hence, this very high temperature is one of the first effects of a nuclear detonation which is different from that of high explosive reactions.

This extremely high temperature which is not very different from that which exists at the center of the sun is accompanied by tremendous pressures, such that at a very few microseconds pressures of the order of many millions of pounds per square inch exist. An expansion, then, of the vaporized bomb materials begins to take place, and at seven-tenths of a millisecond—that is, seven ten-thousandths of a second—the fireball for a 1 megaton detonation will have a radius of 220 feet, and at about 10 seconds will have reached its maximum diameter of about 7,000 feet. This is for a 1-megaton detonation.

This growth of size is accompanied by a decrease in temperature and pressure, the formation of a shock wave which produces the familiar blast effects, and at the same time the fireball will begin to rise and to engulf large quantities of air and other materials, depending on the way in which the detonation takes place. (See pp. 97–98.)

While the ball of fire is still luminous, fission products, fissionable material, bomb casing, and other materials, are all present in the form of vapor. But as the ball of fire begins to cool, these materials condense; they form little globules in the fireball; they are absorbed on particles of dust and dirt which may be present, and eventually start to fall out in the process which will be discussed for you called fallout.

The cloud from a megaton weapon rises initially at tremendous velocity. Its initial velocity may be as much as 250 miles an hour. Consequently, in the first minute the fireball will have risen to a very great height—as a matter of fact, something like 4 to 4½ miles—and hence the radiation which reaches people on the ground in the vicinity can reasonably be divided into two parts: That part which comes in the first minute, which is sensibly that from the fireball, and that which comes after the first minute when the fireball is so far away that it can no longer have an effect and hence this radiation is from that material deposited on the ground, induced activity, or from fallout.

This distinction is somewhat arbitrary and yet it is a useful distinction, and we speak thus of initial radiation as that which occurs in the first minute, and delayed radiation that which occurs after the first minute.

It might indicate to you, because of this distinction, just how the cloud goes as a function of time. If I list the height of the cloud and the time at which the cloud reaches that height, we will say that

the cloud will be at 2 miles in three-tenths of a minute. It will be at 4 miles in three-quarters of a minute. It will be at 14 miles in about 6 minutes.

Representative VAN ZANDT. It is based on 1 megaton?

Dr. GRAVES. This is all for a 1-megaton bomb.

So when we say that the initial radiation is that which occurs within the first minute, we are saying after that the bomb itself is so far away from us that the radiations from the fireball are essentially negligible compared to other kinds. That is basically the distinction between what we call initial radiation and residual radiation.

Clearly this table will vary for different yields or different atmospheric conditions. But it is an illustration of the height to which the cloud will rise in a given time in order just to make clear the distinction between initial and residual radiation.

Dr. Mills this morning discussed for you the fission process. I would like to repeat, to some extent, the information that he gave, in different language, chiefly because I would like to put a little different emphasis on the remarks that he made.

In the first place an atom may be thought to consist of a central nucleus with a number of electrons rotating around it in various orbits. The simplest nucleus known is that of the hydrogen atom which has a mass of 1 and a charge of plus 1. The hydrogen nucleus is called a proton. All other nuclei consist of protons and particles which we call neutrons. The neutron is just like the proton except that it has no positive charge. It has the same mass but has no charge.

For some reason or other, there seems to be a tendency in nature for nuclei to consist of about equal numbers of protons and neutrons. For example, the helium nucleus contains 2 protons and 2 neutrons. One form of lithium nucleus contains 3 protons and 3 neutrons. Carbon contains 6 and 6. Nitrogen contains 7 and 7. Oxygen contains 8 and 8, and so on. This is a general tendency among nuclei. They are stable when they have roughly equal numbers of protons and neutrons.

In the uranium nucleus, which contains 92 protons and 143 neutrons, it is obvious that this is not the case, because now the number of protons is very much less than the number of neutrons.

In the fission process, therefore, when we split the uranium nucleus we tend to have parts which are very rich in neutrons, and hence in the process we would expect to find neutrons being emitted, or neutrons giving up electrons so that the neutrons are converted to protons. Hence in the fission process we would expect to find neutrons being emitted, we would expect to find beta particles (electrons) being emitted, and we would expect to find energy in the form of gamma rays being emitted.

This is the basic origin for the activity and the radioactivity that is produced in nuclear detonations.

In ordinary chemical reactions, the revolving electrons take part, and they are the things which hold the atoms together to form carbon dioxide, water, salt, and so on.

It is the forces that these electrons produce in one way or another which cause the normal molecular reactions to occur.

In nuclear reactions, it is the nucleus which plays an important part. In the fission reaction we have the uranium nucleus, around this we will have 92 electrons. They are not shown on this chart because they have no importance in the particular reaction we are discussing. (See p. 98.)

The uranium nucleus is struck by a neutron. When the neutron strikes the nucleus, it forms a new nucleus which is a form of uranium but is heavier by 1 unit. It will now be uranium 236.

Uranium 236, then, is unstable in a very strange way. It is unstable in that it tends to split to form two pieces. These two pieces are the fission fragments which we have been discussing this morning and which we will discuss from now on in considerable detail.

In addition to the fission fragments, this reaction also gives off a number of neutrons. The number of neutrons will vary, depending on what the fragments are. It may be 3, as shown here, it may be 2, or it may be 4. But it will vary from one nucleus to another or from one mode of disintegration to another.

You have heard at considerable length of the production of krypton, the production of strontium, the production of barium, the production of many things in this sort of process. What comes out depends entirely on how the split takes place. If you take a piece of paper and tear it in half, the two pieces of paper will never be identical if you repeat the process time after time. Similarly here, the way in which the nucleus splits, depends very much on chance. We may at one time have it split the way we have shown here, but at another time we may have a different set of nuclei.

It turns out that fission can happen in some 40 different ways. That is, we may have 40 different pairs of nuclei produced. These nuclei are all radioactive; they all decay, and in decaying go through a number of different stages of decay. All in all, we may find some 200 different radioactive species present in fission debris. That is, there are the original 40 pairs produced by these 40 modes, and all of their daughters and granddaughters, a total of something like 200 different species of radioactive atoms.

I have another chart which shows the way in which this is done. I have listed on the bottom here the masses of these nuclei. Then up the side are listed the percents formed. This says 10 percent of the fission that occur will produce these elements. One one-hundredth of a percent would produce these. One one-hundred-thousandth of a percent would produce these. (See p. 96.)

What we have done is to try to illustrate the relative frequency with which a given mode of fission will occur. You will notice that in fission there is a strong tendency to produce a light fragment and a heavy fragment, and that there is very little probability of producing symmetrical fission, in which the two fragments would be equal. This figure can vary with a particular fissioning material that you use. This chart is drawn for uranium 235. If we were going to draw it for plutonium we would have a slightly different chart. If we were going to draw it for fast neutrons, we would again have a different chart. But for a specific case this is an illustration of the way, or the many ways, really, in which fission could occur.

One would expect, then, from this particular chart to find that masses in the region of 95—somewhere along in here [point to chart] and masses in the region of 140 or something of that sort, would oc-

cur quite frequently. Hence we would expect that we might have a case where strontium 95 was produced as the light fragment and xenon 139 as the heavy fragment. You notice that this strontium 95 is not the strontium that we were talking about this morning. The strontium this morning was strontium 90. This is strontium 95. It behaves like any form of strontium chemically. You cannot distinguish it from normal strontium chemically. But it is different nuclearly. Strontium 90 has a half-life of 28 years. This form of strontium has an extremely short half-life, of the order of a very small fraction of a second. It decays to yttrium 95, and you will recall that strontium 90 also went to an isotope of yttrium, yttrium 90. Yttrium has a different half-life, and for yttrium 95 is very short. These two half-lives are so short we do not know what they are, but they are each a very small fraction of a second. Yttrium 95 then goes to zirconium, and this goes to columbium or niobium, whichever is the name you prefer, and this finally goes to molybdenum, which is stable.

You notice in this process what has happened in that one of the neutrons in the nucleus of strontium 95 has given up an electron and thus converted itself into a proton. The mass has stayed at 95 all the way through the process, but we have lost an electron in each one of these stages, or we have gained one unit of positive charge.

So when strontium becomes yttrium, we have lost no mass, we have lost a negative charge, and similarly here and here [indicating at blackboard] hence this process which I am describing is accompanied by the loss of four electrons, and at each stage gamma rays will be emitted. That is, this strontium will be in a very excited state. In order to lose its excitation it emits a gamma ray or several gamma rays, so that not only electrons but also gamma rays are emitted.

Similarly xenon 139 will also decay with the production of electrons and gamma rays. It goes first of all to cesium 139. Cesium decays to barium. Barium decays to a form of lanthanum, and this is the stable lanthanum, as I recall it.

Again, let me emphasize that in this particular mode of fission which is one which should be most prominent, we have a net effect of the production of seven electrons, numerous gamma rays, and a large amount of energy. This is just an illustration of what may happen.

Other chains that can occur can be different from this but they will have this similarity, that they will produce electrons and they will produce gamma rays, and in the fission process, neutrons will be emitted. Almost never in the fission process are stable isotopes produced. It just so happens that when a fission reaction occurs, the fragments themselves do not appear in the form of stable nuclei. They are always in an unstable form and try to lose neutrons or electrons to become stable.

However, we do find a type produced which will have only 1 stage, or perhaps 2 stages of decay before becoming stable. Then we will have some which produce very many more. We have several that will produce as many as six. For example, krypton 97 among the light elements, and xenon 143 among the heavy, produce the longest decay chains that we know of. Each one of these has six stages of decay. Each emits six electrons and many gamma rays.

Senator BRICKER. Does the breakdown in krypton follow the same line as it does in the 95 group?

Dr. GRAVES. Yes, it is exactly the same process. You will have six stages. Here you lose one electron—that is, you go from krypton to the next element and so on—you do not change the mass at all. There are a few cases, and only a few, where instead of losing an electron like this, you will lose a neutron. This is a very rare occurrence and is the origin of the delayed neutrons. Almost invariably the decay process is similar to the one given here.

Senator BRICKER. You say that krypton 97 gives off six products in the decay process. What are the additional ones?

Dr. GRAVES. I don't have them here. It ends up again in a form of molybdenum. I can list many of them.

Senator BRICKER. It is the same end result?

Dr. GRAVES. Yes, sir. Instead of being molybdenum 95 it is molybdenum 97. Then there will be niobium, zirconium, and yttrium 97.

Senator ANDERSON. How do you know whether it will be strontium 95 or strontium 97? You end up with strontium and molybdenum 95 which you say is relatively harmless.

Dr. GRAVES. It is stable.

Senator ANDERSON. When do you get to the strontium 90?

Dr. GRAVES. We started out with this element with a mass 95. If we start out with an element of mass 90 right here then we would have ended up with strontium 90. That also is a very prominent member. It happens quite frequently.

Senator ANDERSON. Let me ask it this way, Doctor Graves: Are there any statistics showing how frequently this fissioning results in strontium 90 and how frequently it results in strontium 95 or strontium 97?

Dr. GRAVES. That is what this chart shows.

Senator ANDERSON. That is what that chart shows?

Dr. GRAVES. This says that in about 5 percent of the cases the chain which includes strontium 90 occurs. It may vary from 3 percent to 5 percent, but it is about that number.

Senator ANDERSON. In other words, one-twentieth of the time, you would say?

Dr. GRAVES. Yes, sir.

Senator BRICKER. Is your molybdenum 97 found in nature?

Dr. GRAVES. Yes, sir.

Senator BRICKER. All of the end products of these decaying processes are natural elements?

Dr. GRAVES. Yes, sir.

Senator ANDERSON. Then if there is discussion of bombing and people talk about strontium 90, there is a possibility that several bombs might be exploded and no strontium 90 at all exists.

Dr. GRAVES. As long as fission occurs, the probability is 1 in 20 that roughly 5 percent of the fragments which are produced will be strontium.

Senator ANDERSON. It is a fairly regular pattern that happens in most explosions where a portion of it is strontium 90, a portion is 95, and a portion is 97, but it is a relatively small portion?

Dr. GRAVES. As a matter of fact, when scientists are discussing the things that we do not know, or the things that we disagree on, this is not one of them. Data of this sort—the real input data—is very well

known. The question is on what effect this will have on a human being. I do not want to discuss that. This part is known.

Senator ANDERSON. Cesium 139 has some members of its family that are destructive.

Dr. GRAVES. Yes. Strontium 90 as you recall gives out beta particles. It emits no gamma rays. Hence it is only important if it is inside the body as an ingested material. I am talking out of my field but if it goes to the body it goes to the bones and there it has its effect. Cesium is not that way. Cesium is a gamma emitter and hence it can be important as a part of the external dose. It is a relatively prominent fragment. Cesium is formed in something like 5, 6, or 7 percent of fissions.

Senator ANDERSON. That is what brings me to say that even though strontium 90 is not formed, there may be a strontium figure, which I assume is somewhere around 97, which will produce some cesium 137.

Dr. GRAVES. That is correct.

Senator ANDERSON. And that is somewhat dangerous.

Dr. GRAVES. Yes. As a matter of fact, all of these fragments, as I will discuss in a minute, contribute to a hazard which we call the residual hazard, or what is left over after the detonation. In fact, this is the hazard, the things that are produced here are the things which are giving out gamma rays, beta rays and so on, and which produce the biological changes with which we are concerned.

Senator ANDERSON. So practically up and down that scale you have products that could be harmful.

Dr. GRAVES. Products that are harmful.

Senator BRICKER. What is the half-life of cesium 139? Is it a fast decaying element?

Dr. GRAVES. It is relatively fast. There are only a relatively few that are quite long. Strontium 90 is one of them, being 28 years. Cesium 137 is also long. Those two are the main fragments which are left after times like years. Those are the ones that you have to worry about. The others are all decayed by then.

Senator BRICKER. They are gone in a day or two?

Dr. GRAVES. Not in a day or two, but inside of a year.

Senator ANDERSON. It is because of this half life of strontium 90 that runs 28 years that we talk about it and worry about it more than we do 95 or 97 or any other number?

Dr. GRAVES. Exactly.

Senator ANDERSON. We are worrying about the length of time. The immediate bursts go quickly and then we worry about the long life of strontium 90?

Dr. GRAVES. Yes. It happens that this is exactly the wrong half-life. If it were very short it would be gone so fast we would not worry about it. If it were 1,000 years it would decay slowly. 28 years being comparable with the human cycle is just the wrong period. It has the maximum activity and still present with us for a long time.

Representative HOLIFIELD. Do you intend to get into the factor of the amount of this material that goes into the stratosphere and the amount that is left upon the earth in the initial explosion and the rate of fall from the stratosphere of the amount that goes in? Had you intended to comment on that?

Dr. GRAVES. No. It was my understanding that would be taken care of by the next speaker.

Representative HOLIFIELD. Very well.

Senator PASTORE. How do we know it has a 28-year half-life?

Dr. GRAVES. One can measure it very accurately, Senator Pastore. What we do is to measure the activity today and tomorrow and the next day. One sees it dropping off. So if you have 100,000 disintegrations now—suppose that a year from now you had half as many disintegrations—you would know that half of it was gone. So by following the decay one can determine just how long it takes for half of it to disappear.

Representative COLE. What is the explanation of why some form of strontium has a longer half-life than others?

Dr. GRAVES. It depends on how nearly stable it is. One form of potassium is almost stable. It is just barely over the edge. If it is just barely over the edge it takes quite a time for it to fall off.

Representative COLE. Stability is a substance that has no half-life.

Dr. GRAVES. Exactly. If you were to plot the normal elements, plot the number of neutrons against the number of protons, there is a great tendency for the number of neutrons to equal the number of protons. So among the light elements this is a straight line at 45 degrees. They all have an equal number of neutrons and protrons.

If for some reason or another you produce an element which has a different number of neutrons it is very unstable. If it is closer to this line it is less unstable. Finally when it is nearly on the line it takes many, many years for it to decay. It depends how near it is to this line. If you get up to uranium or the heavy end, this line curves up and you find we have a tendency to have more neutrons. But within, you will have a case like this [drawing curve on blackboard]. Anything within this band is stable. There will be a lot of individual points but they are all within a band like this. Outside of this region they are unstable.

So it depends on how far outside this band they are as to what their half-life tends to be.

Representative COLE. That is not quite it. What is there about a strontium 90 that gives it a comparatively long half-life but strontium 95 a negligible half-life?

Dr. GRAVES. Strontium 95 is just much less stable than strontium 90. It is very far off stability.

Representative COLE. What is there about it that gives it a much less stability?

Dr. GRAVES. Strontium 90 has many less neutrons.

Representative COLE. The difference between 95 and 90?

Dr. GRAVES. Yes.

Representative COLE. Does strontium 95 have the same effect on the anatomy as strontium 90?

Dr. GRAVES. If it were present in you? No. Strontium 95 not only gives off beta rays but it gives off gamma rays, whereas strontium 90 gives off only beta rays. In addition, strontium 90 stays with you for a long time. So it can become fixed in your bones and it can irradiate the material of your bones. Strontium 95 has such a short life that it never becomes fixed in the body. You do not have time to eat it and then have it converted into body tissue.

Representative COLE. If it did stay longer it would have the same effect?

Dr. GRAVES. Or even worse because of the gamma rays it produces.

The fusion process is quite different from the fission process. Among the light elements, there is a tendency for the energy per nuclear particle—that is, per proton and neutron—to decrease with increasing weight as contrasted with the fission process, in heavy elements, where it increases with increasing weight. Hence whereas in the fission process we tend to gain energy by splitting a nucleus, among the light elements we tend to gain energy by combining nuclei—by joining them together—and hence by a process which we call fusion.

Again I may be repeating to some extent what Dr. Mills said this morning, but I would like to list for you the reactions in deuterium which are important from the point of view of fusion because this again illustrates the important difference between the fission process and the fusion process as far as production of radioactivity is concerned.

Whereas in the fission process I have said there might be as many as 40 different modes that can occur—40 different ways in which the fission process can occur—there are only two ways in which the fusion process of deuterium can occur. We may have deuterium joining with another deuterium atom to produce a different form of hydrogen. Deuterium which is a form of hydrogen has a proton and a neutron in the nucleus. The fusion reaction may form still a third form of hydrogen, which we call tritium, where tritium has 1 proton in the nucleus and 2 neutrons.

Tritium plus a proton or helium 3 plus a neutron may be produced.

In each of these cases energy will be produced. In the first case there will be 3.2 Mev. Did Dr. Mills explain this term?

Representative HOLIFIELD. No.

Dr. GRAVES. A million electron volts is the energy an electron would have if it fell through a million volts. If you take it from here and apply a million volts to it, when it gets down to here it will have this amount of energy. It is like saying it has so many foot-pounds of energy, or what-not, but it is a number giving us a measure of energy. In this case we would also produce energy and it would be 4 Mev.

The net result of this fusion reaction, is that we have helium which is stable. We have protons which are simply the nucleii of hydrogen atoms which are stable. We have neutrons. Then we have tritium which is unstable.

Tritium itself may unite with deuterium and if it does it will produce a form of helium—normal helium, as a matter of fact—at mass 4, and it will produce a neutron.

In this case, we have used up our radioactive atom tritium and produced stable helium. Again we have a large amount of energy produced. This produces 17 million volts of energy.

Then finally, under certain circumstances we may have these helium 3 nuclei uniting which will produce helium 4, plus 2 neutrons. This time we will have 11 million volts.

The point that I am making is that in each of these reactions we have energy produced. In the net of all of these reactions we have many neutrons produced, but we have no radioactive materials produced, with the exception of tritium, which is also itself used up in subsequent reactions with deuterium, and this is a very probable reaction.

This, then, is the difference between the fusion reaction and the fission reaction. Although we have also large amounts of energy produced, we have very small amounts of radioactivity produced directly. We may still have radioactive materials produced by action of these neutrons on substances that are present. I will discuss this when I discuss induced activities.

We have now discussed the production of radioactive materials in the fission process, the production of radioactive material, such as it is, in the fusion process.

The third source of radioactive materials is in the induced activities which are caused when these neutrons react with substances that are available.

Chairman DURHAM. Did you say what degree of heat you get in either one of those final chain reactions?

Dr. GRAVES. If you take a pound of deuterium and somehow or another burn it all—that is, burn the whole pound of it—you will get the equivalent of 26,000 tons of TNT. That is the amount of energy that you would get from 1 pound of deuterium. The temperature will depend on how much material you apply this energy to. But this is the amount of energy you would get out of a pound of deuterium burning completely.

Representative VAN ZANDT. That is about 1 cubic inch.

Dr. GRAVES. No. It depends on what form it is. It is a gas. It depends on its pressure. A pound of uranium, I said, was about a cubic inch.

Is that sufficient for your purposes, sir?

Chairman DURHAM. Yes.

Dr. GRAVES. Normally, the radioactive materials induced by neutron capture in dirt or in bomb materials or in air will have a very short half-life, or they will have a long half-life but will have such small energies in their decay particles that they will not be important.

Consequently, we may say that the induced activities are not going to be a tremendously important worry or concern in this problem. For example, nitrogen in the air can capture neutrons to become carbon. It becomes a form of carbon which is radioactive, but it is radioactive with a half-life of 5,000 years. Consequently, although it is around a very long time, and although it may take its place in our bodies, it has very little energy in the particles which come from it. It has very low activity, and the amount that we can produce is extremely small compared to the amount which occurs naturally in nature.

Therefore, radioactive carbon itself is not an important activity.

We may have others, however. Oxygen can absorb fast neutrons and in so doing it forms an isotope of nitrogen which has a half-life of only 7 seconds. Since the half-life is only 7 seconds, within a minute essentially all of this nitrogen will be gone. In 6 half-lives—(I guess that term was discussed this morning)—the amount is reduced to something like 1 percent. In 10 half-lives it will be produced to a tenth of a percent. So in 70 seconds, or a minute and 10 seconds, there will be only one-one thousandths of the nitrogen remaining.

Chairman DURHAM. Do you get a chain reaction, Doctor?

Dr. GRAVES. No, sir. One of the important components of any residual activity will be due to 14.8-hour sodium; 14.8 hours is suffi-

ciently long so that it will be with us for a fair length of time, and yet it is sufficiently short that we will be able to have enough activity to make itself noticed. It is formed when ordinary sodium captures a neutron. Ordinary sodium is present to a very considerable extent in the form of sodium chloride, or salt, particularly if we are in the neighborhood of salt water. We will have large amounts of this type of sodium formed. Again, however, it will disappear in time. Say the half-life is 15 hours—it is a little less than that—this means that in something like 90 hours there will be only 1 percent of it left; 90 hours is roughly 4 days, so that inside of a week there will be very little of the sodium left. Whereas, the fission products will be with us for some time.

Silicon 31 is another one that is formed in very appreciable amounts, largely because there is a considerable amount of silicon present. It is formed when normal silicon captures a neutron. It, however, again has a half-life of only 2.6 hours and hence it decays very rapidly.

Aluminum 28, which again is quite abundant (aluminum is quite abundant—when it captures a neutron it forms aluminum 28) has only a half-life of a few minutes and hence will completely disappear within the first hour.

Chlorine produces a 37-minute activity. This emits betas and high energy gammas but again 37 minutes is so short that it will not be with us for very long.

The only other things that one should mention is that materials of construction, materials which are commonly used, such as zinc, copper, iron, glass, or the salt in foodstuffs, might under some conditions become active enough to become significant.

The net effect of what I have said, I think, is that although induced activities are present, although one can measure them, one can anticipate them, their effect will never be more than a few percent of that of the fission products themselves.

So that in our worries, or in our concern over the activities accompanying atomic detonations, I think it is fair to say that the induced activities are not the important source of radioactive materials or radiation.

Now, if I may leave the subject of radioactive materials and their production——

Representative HOLIFIELD. Before you leave that, Doctor, how do you explain the persistent radioactivity of the coral in the lagoons where these detonations have taken place?

Dr. GRAVES. Largely because there is deposited on this coral fission fragments themselves. When you detonate an atomic weapon on the surface—any surface—you bring up into the cloud large amounts of dust particles. These dust particles are in the cloud along with all of the fission fragments and all the fissioning nuclei, and they are stirred up together and all of the fission fragments must condense from the gaseous form onto something and they condense on whatever particles are there. If we have particles of coral they will condense on coral. In Nevada they will condense on dust particles. So what we have is a coral on which has been deposited fission activity.

Representative HOLIFIELD. So the long-lived activity of materials other than fission materials is caused by the adherence of the fissionable materials to the spectrums of matter, whatever they may be, whether it is dust or coral; is that right?

Dr. GRAVES. Yes.

Representative HOLIFIELD. The matter becomes a carrying element for the fissionable element.

Dr. GRAVES. It is important because it may bring the material down to the ground sooner because it is heavy. In that way it can have an important effect on fallout, as Mr. Kellogg will discuss next. It may also have some activity, like calcium in coral. The calcium of calcium carbonate may become active. Such activities almost invariably decay in such a short time that they may be ignored insofar as the fission-fragment activity is concerned.

Representative VAN ZANDT. Is there any uniformity as to the amount of particles lifted into the atmosphere from a megaton or kiloton of yield of the weapon?

Dr. GRAVES. Yes. You will get an argument from lots of people on this, but my number is that something like a megaton of energy will lift up a tenth of a megaton of dirt. This is rough. It depends a lot on what the dirt looks like and so on, but it is something of that order.

Representative VAN ZANDT. The greater the yield then the higher the particles are lifted.

Dr. GRAVES. That is roughly correct; yes. It depends not only on the yield but the atmospheric condition, as I mentioned before.

Representative HOLIFIELD. In evaluating the radioactivity in a bomb, we must take into consideration the amounts of matter which are contacted by the fireball of the bomb?

Dr. GRAVES. Yes.

Representative HOLIFIELD. It is obvious that, if a fireball is touching the ground or coral reefs or anything like that, it would produce a great deal more radioactive material than if exploded a mile high in the sky.

Dr. GRAVES. No, the difference is not so great. The amount of radioactive material produced will be very little different. It will be some because of the induced activity.

Representative HOLIFIELD. But the dispersion of it, because of its lack of attachment to matter which gravity would have an effect upon, would be completely different.

Dr. GRAVES. That will be completely different; yes, sir, and that is the importance. If you detonate it on the surface of the ground or below ground, then you will have a very strong tendency to have the radioactivity deposited locally. If you put it high up in the air you will have about the same amount of activity. Less will be deposited locally but more will be deposited worldwide.

Representative HOLIFIELD. Is it not true also that the higher you go with the bomb the less you take advantage of its energy release as far as destruction is concerned?

Dr. GRAVES. No, sir. As far as blast effects are concerned, there is a height which seems to be optimum for a given yield. This is not way high up in the air nor on the surface; if you are interested in maximizing blast damage you will pick a certain height. Similarly if you are interested in maximizing thermal damage you will not have it on the surface because on the surface one building will be shielded by another and hence thermal radiation will hit one and burn it completely but will not touch the other. Whereas, if you have it up high you will be able to get both buildings.

Representative HOLIFIELD. But in each case when you go above that set point, you lose efficiency.

Dr. GRAVES. Exactly.

Senator BRICKER. Doctor, you mentioned a moment ago that nitrogen would pick up one neutron and become carbon. That is carbon 14 with the long half-life?

Dr. GRAVES. That is right.

Senator BRICKER. That is the one of Doctor Libby's age determination?

Dr. GRAVES. Yes, sir.

As I mentioned earlier, initial nuclear radiation is defined as that radiation which is delivered during the first minute. I would like to spend a minute discussing initial radiation for you. Although initial neutrons and gamma rays constitute only about 3 percent of the energy of the detonation—that is, 3 percent of the bomb energy comes out as initial neutrons and gamma rays—a very considerable portion of the bomb casualties are caused by these neutrons and gamma rays.

You might compare this with thermal radiation, in which something like a third of the bomb's radiation will come out as thermal radiation. Let me say 33 percent. So here we have 3 percent coming out as neutrons and gamma rays and yet this 3 percent is an extremely important part of the effects that you observe in the detonation.

In order to indicate the magnitude of this effect, I might give as an illustration the following: 50 percent of the people shielded by as much as about 2 feet of concrete would be killed by the initial gamma rays and neutrons 1 mile from a 1-megaton bomb.

Let me put that on the blackboard for you. If I had a detonation of a 1-megaton bomb, and a mile away from that had a shelter whose walls were 2 feet thick, 50 percent of the people in that shelter would die. Whereas, with thermal radiation we could have a very much lighter shield at this same point and provide complete protection. That is why initial radiation is an important part of bomb detonations.

Representative VAN ZANDT. Doctor, how much concrete would be necessary to shield a person from a 1-megaton blast?

Dr. GRAVES. That is just on the edge. If it is 2 feet thick I say about 50 percent of the people would die. If we increase it to 3 feet thick, the chances are that practically everybody would live. This is just on the edge of being sufficiently safe.

Senator PASTORE. That is the question I was going to ask. Why would 50 percent die and not all of them die? Why would 50 percent be vulnerable and why 50 percent not? If you are hit, you are hit.

Dr. GRAVES. It is like when we have pneumonia. Some of us die and some don't. It is partly chance. It is partly how healthy we are. It is partly the condition we are in. This is just the mean lethal dose. This is right on the edge. If it gets much bigger, everybody will die; if it is much less nobody will die.

Senator PASTORE. How do you scientifically assert that? How do you prove that?

Dr. GRAVES. That is hard. The basis for it, however, is experiments with mice or rats, finding out what the mean lethal dose is for a long chain of animals. I would much prefer that you ask that sort of question of a biologist who knows it better. This is the basis for such

a statement. You go on the basis of experiments with animals to find it out.

Senator PASTORE. In other words, we have determined that with animals in blast situations, just as you have outlined, some have died and some have not?

Dr. GRAVES. That is right.

Chairman DURHAM. It is a proven and known fact, Doctor, is it not, that radiation dies in some individuals quicker than in others?

Dr. GRAVES. Some people are more susceptible to damage from radiation, just as in the case of pneumonia. I imagine that is your question.

Chairman DURHAM. The radiation itself dies more quickly in an individual.

Dr. GRAVES. The radiation will depend on the substance. Carbon 14 has a half lifetime of 5,000 years. It does not make any difference whether it is my tissue or yours. Sodium has a half-life of 14.8 hours. There is nothing we can do physically to change that half life. We can heat it up, cool it down, physically distort it in any way we want, but we cannot change the fact that in 14.8 hours half the sodium we have now will be gone. That is just the way radioactivity is.

But the effect of radiation on you may be slightly different from its effect on me.

Representative HOLIFIELD. The effect on a child, for instance, might be much greater than on an adult.

Dr. GRAVES. That is possible; yes.

Senator ANDERSON. Before you get away from the diagram you have there, you show deuterium, plus deuterium, and then doing some other things, and tritium coming in, and you said something about less fission in that sort of operation.

Dr. GRAVES. I said less radioactivity. There are no radioactive materials here except tritium. The tritium itself may be absorbed by deuterium to form normal helium.

Senator ANDERSON. Is there not radioactivity in all fission? In every fission process there is some radioactivity?

Dr. GRAVES. Yes. This fusion and this other is fission.

Senator ANDERSON. In order to have the fusion you are talking about there has to be some fission. I won't say how much.

Dr. GRAVES. This is a fusion reaction but it also can be maintained by heat. If we can somehow or another get this deuterium hot enough it can also be made to react. Hence it is carred a thermonuclear reaction as well as a fusion reaction. One of the ways of getting it hot enough might be to use fission.

Senator ANDERSON. You have not done it any other way, probably, so if you do use fission then any bomb that involves fission will have radioactivity in it.

Dr. GRAVES. I would prefer not to discuss that in an open meeting, Senator.

Senator ANDERSON. That is the trouble. I don't blame you.

Dr. GRAVES. I do not want to discuss how a bomb works.

Senator ANDERSON. I was trying to get around to the claim we have a clean bomb, which I do not believe we have. I did not know whether this was a good place to get it or not.

Dr. GRAVES. I will be happy to discuss that with you personally at any time.

Representative HOLIFIELD. These statements have been made publicly about these clean bombs. I would say this much, without going further into it at this time, that as long as statements have been made that there is a clean bomb some clarifying statement should be made in these hearings.

Dr. GRAVES. I have here a set of processes which involve production of no radioactive materials. I have here a process which involves the production of very large amounts of radioactive materials. As Senator Anderson has pointed out, there is a possibility of a combination of these two processes. If you have a large amount of energy coming from this fission process, there is nothing you can do but produce radioactive materials. If somehow or another you can arrange your geometry or your procedure such that you produce more of your energy from these processes (fusion) then you have less radioactive material for the energy you produce.

Senator ANDERSON. You have a cleaner bomb but you do not have a clean bomb.

Dr. GRAVES. Exactly.

Senator ANDERSON. That is exactly the point. Every time you try to get into a discussion of it—I am not complaining about your attitude on it—we find it is not the best thing to discuss in public, and you are glad to discuss it with me privately and I find it very profitable to discuss it with you privately.

But that does not help the people who read a news story that we have a clean bomb which some of us believe is a true statement.

Dr. GRAVES. I agree with you thoroughly. The statement should be a "cleaner" bomb.

Representative HOLIFIELD. People are being blamed about being confused. Some of the statements that have been made by AEC members and distinguished scientists along this field are directly attributable to part of this confusion that exists. It is the intent of these hearings to clear up some of this confusion, within the limits of declassification. I do not believe that the committee will want to accept everything that we try to do to clear up the confusion, as being classified.

Dr. GRAVES. I do not think one would ask you to do that either. What I would prefer would be to have a chance to discuss this with you privately and let you decide whether it is what you want to accept as classified or whether it is important for your discussions publicly.

Senator ANDERSON. May I say, Doctor, my sole purpose is to try to find out occasionally if there is a chance to clean this up. The only way is to ask witness by witness until we finally come down to a spot where it may be convenient to clear it up. It is not meant to be critical of you in the slightest.

Representative HOLIFIELD. No. This committee is not responsible for the phrase "clean bomb." We are not responsible for it. But there are millions of people throughout the world that may be hanging their hopes upon the fact that we have a humanitarian hydrogen bomb.

Dr. GRAVES. I am afraid the only comment one can make on it is that "cleanliness" is a little bit relative anyway. What you mean by "cleanliness" in this case is a question of degree.

Representative HOLIFIELD. You would not say in this case that cleanliness is next to godliness.

Dr. GRAVES. No. As Senator Anderson says, complete cleanliness is next to impossible to achieve.

Senator BRICKER. May I ask how much earth it would take of ordinary character or texture to give the same radiation shielding that 3 feet of cement would give?

Dr. GRAVES. Yes. It is almost directly proportional to the density. If you have well-tamped earth, something like twice as much earth would be about equally effective.

The initial radiation from all of these radioactive materials or from all of these detonations will consist of alpha particles, beta particles, neutrons, and gamma radiation.

The alpha particles can come from two sources. In the first place, the fissionable materials are radioactive in such a way as to produce alpha particles. So that uranium, plutonium, whatever materials of this sort are present, will produce alpha particles.

In addition, in the fusion reaction we have the production of alpha particles. Here is an alpha particle, here is one, and this would actually be similar to an alpha particle [indicating on blackboard] and there are other alpha particle reactions which are possible.

Neutrons can be absorbed in materials to produce alpha particles. So the two sources are in the heavy materials which are present and in the various alpha-particle-producing neutron reactions which can take place.

As Dr. Mills mentioned to you this morning, alpha particles have an extremely short range. They will scarcely get through the dead skin on the surface of your body, and hence as far as the initial radiation is concerned, are of almost no importance.

Beta particles have a somewhat greater range than alpha particles. They are also produced in large numbers in the various processes that occur. But again they have a short range, such that they cannot reach the ground from an air burst, and within a very short time, when the cloud rises, they will not be able to reach the ground from any sort of a burst, and hence they also are not of great importance as far as the initial radiation is concerned.

Other speakers later will talk about the importance of alpha radiation and beta radiation as far as the internal hazard is concerned and as far as contamination on the skin is concerned. I do not propose to go into that. I would rather limit my remarks to the discussion of gamma radiation and neutron radiation as they effect the initial radiation hazards.

Both neutrons and gamma rays can penetrate air to very considerable distances. They are both highly injurious to living organisms. Hence they constitute by far the most important part of initial radiation.

To a great extent neutrons come out in a very few milliseconds—the first few milliseconds of the detonation—when the bomb will be a very compact, dense material still, and hence these neutrons are very largely absorbed in bomb materials. Enough fast neutrons, however, are present to constitute an appreciable direct hazard at consideraable distances.

Similarly, the gamma rays which are associated with the fission process itself—gamma rays that come out in the initial stages of the fission process—are also present in the stage when the bomb is con-

densed, heavy material, and hence these gamma rays are highly absorbed.

Only about 1 percent of the gamma rays produced directly in fission escape the immediate region of the detonation. However, again this contribution and that of the gamma rays produced in other processes which I will discuss in a minute will produce sufficient intensity at considerable distances to constitute a very real hazard.

Let me mention some of the sources of the gamma radiation which is present in initial radiation.

In the first place it originates in the fission reaction—the one that we picture here.

Second, gamma rays can appear in various neutron reactions.

First, neutrons may be captured with the formation of a highly excited compound nucleus. This compound nucleus loses its excitation—that is, returns to its normal state—by emitting a gamma ray. For example, when neutrons are captured to form carbon 14, in the process of being captured, nitrogen 14 is formed in a highly excited state. This produced two gamma rays which are high-energy gamma rays and emits them. Nitrogen 14 captures a neutron to become nitrogen 15. The nitrogen 15 emits a proton to become carbon 14. But in this process the compound nucleus releases these two high-energy gamma rays.

In the second place, neutrons may react with nuclei, emitting protons or alpha particles, and gamma rays are frequently emitted in this process.

Finally, neutrons may bounce off other nuclei, and they may bounce inelastically such that the bombarded nucleus becomes excited and emits gamma rays.

The third important component or part of the gamma rays in initial radiation is from fission fragments. Fission fragments can be widely spread, and as they decay can give off gamma rays. Many of these gamma rays are given up in the first minute and hence are properly included in the initial radiation.

Although instantaneous and delayed gammas are produced in about equal amounts, the instantaneous gammas are absorbed so strongly that they constitute only about 1 percent of the external dose received. Hence 99 percent of the external dose is due to the so-called delayed gamma radiation. It will probably be of interest to discuss at least briefly the dose distance relationship for both gamma rays and neutrons, that is, how far from a given detonation would someone receive what dose.

Gamma rays lose energy in going through matter by both excitation of atoms and ionization of those atoms. In fact, it is believed that the chemical decomposition of molecules caused by this effect is the major cause of injury to animals and plants. Consequently, the dose of gamma rays is defined and is measured in terms of the ionization produced.

The dose distance relationships for gamma rays and neutrons are very complicated because of the large number of effects involved. Consequently, I would like to ask you to consider what I say from now on in this respect to be quite approximate. It is not possible to write down an exact analytical expression for the dose-distance relationship.

Representative HOLIFIELD. Dr. Graves, are you going to use chart 6 and chart 7 in your presentation?

Dr. GRAVES. I would like to discuss, if I may, the surface burst and the characteristics of an air burst as they relate to fallout. I will use those. Would you like to have me show them?

Representative HOLIFIELD. These are the charts which you furnished us with your statement.

Dr. GRAVES. I will use those; yes.

Representative HOLIFIELD. I think it would be illustrative if you do.

Dr. GRAVES. I will use those; yes.

It turns out that gamma rays going through air will decrease because of distance, and this decrease is a decrease as the square of the distance.

Gamma rays as they go through air will decrease because of many effects. They will be scattered. They will be absorbed. They will lose their energy. But it turns out that the gamma ray dose decreases by a factor of 10 every 780 yards. Consequently, we have a relationship for gamma ray dose which depends on the yield, depends on the distance squared, and then it drops as an exponential which is given by E to the minus D over 338.

$$\text{Formula: Dose}=\text{Const.}\ \frac{W}{D^2}\ e^{-D/338}$$

This says that dose drops by a factor of E every 338 yeards or by a factor of 10 every 780 yards.

Then there is a constant multiplier. This is an extremely rough formula. For yields from a kiloton up to something like 80 kilotons, it is about correct. If we get much above 80 kilotons, say 100 kilotons, one should multiply the yield by 1½, so it is about 50 percent off there. If one is talking about a megaton, then one should multiply this by a factor of five or something like that. Roughly as far as distance dependency is concerned, the formula can give at least approximate results.

One may do a similar thing for the neutrons. The neutrons again are a constant times the yield divided by the distance squared, and then an exponential term. The neutrons are absorbed more quickly than the gamma rays. The exponential will contain D over 242. If I put it in the same terms that I did for gamma rays, I would say that neutrons decrease by a factor of 10 every 560 yards. So that neutrons will not go as far as gamma rays.

$$\text{Formula: Dose}=\text{Const.}\ \frac{W}{D^2}\ e^{-D/242}$$

The residual radiation—what is left after the bomb has gone off, after the cloud has gone up in the air and after the fallout has occurred—can also be discussed briefly. In the first place, about a tenth of a pound of fission products are produced for each kiloton of fission energy. The radioactivity at 1 minute would be comparable with that of many pounds of radium. Consequently, a megaton of fission energy would result in activity at 1 minute comparable to that of many tons of radium.

I heard somewhere recently that the total world's production of radium since the beginning of time was something like 50 pounds, so that when we talk about the detonation of a megaton, we are talking

about the production of many times the activity of all the radium which has ever been produced. During the first 24 hours, there would be a decrease by a factor of more than 6,000 in the total activity present and then it will decay continuously. But it has been estimated that if all of these fission fragments from a megaton of energy were spread uniformly over 10,000 square miles, it would cause a radiation intensity after 24 hours of 2.7 roentgens per hour. Consequently, unprotected personnel in that 10,000 square miles would receive more than 300 roentgens of radiation after the first day. 300 roentgens is a lot of radiation. It is estimated that something like 450 is the mean lethal does. So 300 is approaching a lethal does.

Representative VAN ZANDT. Then it would be a uniform distribution over the area.

Dr. GRAVES. That is a uniform distribution over 10,000 square miles which would not happen.

Representative HOLIFIELD. But is it not true that there is no such thing as a uniform distribution?

Dr. GRAVES. Exactly.

Representative HOLIFIELD. This starts at many thousands of roentgens near the bomb and it gradually decreases.

Dr. GRAVES. Yes, sir. Again this will be discussed in the next section of the hearings. I don't want to discuss actual patterns on the ground, but I did want to give an idea of what we are talking about in a rough order of magnitude sort of way.

I would like also to give an idea of the rapidity with which the material will decay. So I will give a table of activity as a function of time. Again let me confine this to a 20 kiloton—a so-called nominal bomb.

At the end of 1 minute, the total activity will be equal to 820,000 magarcuries. A curie is the activity of 1 gram of radium. A magacurie would be the activity of a million grams of radium. So we are saying that at 1 minute the activity would be the equivalent of that of 820,000 million grams of radium.

At the end of 1 hour, this will be down to 6,000 megacuries. At the end of 1 day this will be down to 133 megacuries. At the end of a week it will be down to 13. At the end of a month it will be down to about 2. At the end of a year it will be down to 0.11. Then may I finish this off by saying that at 100 years it will be 0.0006.

This morning you asked Dr. Mills the question, how long would it take this to disappear completely. I could go on for a thousand years and a million years, and I would still get something here, but it gets pretty small. Roughly one can say that for a period of time equal to 7—like 7 days or hours—the activity decreases by a factor of 10. So if we say that the activity at the end of 1 hour is something, then at the end of 49 hours—that is 2 days—it will be down by a factor of 100. In 2 days we have lost a factor of 100. In 2 weeks we will have lost a factor of a thousand. This gives you some idea, I think, of the speed with which this residual radiation will disappear.

Representative HOLIFIELD. In order to be clear on this, Dr. Graves, we are talking about a 20,000-ton bomb.

Dr. GRAVES. Yes, sir.

Representative HOLIFIELD. In the case of a megaton bomb, what is your residual radioactivity danger, and let us go from that and extrapolate it to a 10-megaton bomb. I do not ask for the exact figures.

Dr. GRAVES. We can give them. Let me restrict my answer to those in which the energy comes from the fission process. I don't want to get mixed up in the fusion-fission business again. It will depend exactly on the ratio of yields, A megaton is 50 times as much as a nominal bomb yield. If I multiply by 50, I would get the corresponding numbers for a megaton.

Senator BRICKER. But the time would be the same.

Dr. GRAVES. Yes, sir. I would multiply each one of these numbers by the same factor.

Senator BRICKER. The same ratio of decrease?

Dr. GRAVES. That is right.

Senator ANDERSON. In order to help the record out without making it too damaging, would it not be fair to say, Dr. Graves, that an average megaton bomb at the present time at least would probably not be all fission?

Dr. GRAVES. That is correct.

You have asked that I discuss with you to some extent the partition of energy from a nuclear detonation. I would like to preface my remarks by saying that there really is no correct partition of energy. In the initial stages, we have heat—thermal energy—and in the final stages we have thermal energy. Everything else is thermal initially and ends up as thermal. In between it can be converted into nuclear radiations, shock energy, or thermal radiation. So we are talking about something which is changing and the percentages that I gave are not something which you can say will happen after 2 weeks or at any specific time.

This is a rough estimate [pointing to chart] of the way the energy from a typical air burst will be partitioned. Roughly half of the energy will come out as blast or shock wave. Roughly a third or 35 percent of it will come out as thermal radiation. The initial nuclear radiation—that is, that which comes out in the first minute—is only about 5 percent. Whereas, the residual nuclear radiation, that which comes from deposited fission fragments and from induced activities is about 10 percent. As I say, these numbers sort of interchange back and forth. Blast and shock eventually go into heating up the air and become thermal radiation again. Similarly the residual nuclear radiation, the neutrons and gamma and beta rays come out and heat up the air a little bit, and hence become thermal radiation. So this chart is correct at some time, but the partition of energy changes from the first instance to longer times. Moreover, it depends to some extent on the yield of the weapon, the amount that comes out as thermal radiation might vary depending on what the conditions of the weapon itself are. (See p. 97.)

Representative HOLIFIELD. Dr. Graves, will you explain to me what you mean by "thermal radiation"? Do you mean the heat that goes with the explosion?

Dr. GRAVES. Yes. It is the same sort of energy that you detect when you stand in front of a radiant heater or if you open the door of a furnace. You feel something hot on your face. Those who have been out to Nevada have felt this.

Representative HOLIFIELD. If we talk about the total radiation of the bomb, we are talking about this 15 percent that you speak of here. That becomes 100 percent when you talk about total radiation.

Dr. GRAVES. This 15 percent is the total nuclear radiation. This thermal radiation is something quite different. It is just something because the materials are hot.

Representative HOLIFIELD. In testimony before another congressional committee, Dr. Libby said that in the case of one of these megaton bombs, and I believe it was a 10-megaton bomb he was testifying about, that 25 percent of the radioactivity was the part that caused the downwind pattern of 7,000 miles in the testing grounds of radioactive fallout; 75 percent of it went up into the troposphere and stratosphere. Is that according to your understanding?

Dr. GRAVES. What he was talking about in that case would be the nuclear radiation itself.

Representative HOLIFIELD. Yes.

Dr. GRAVES. Let me say the residual radiation.

Representative HOLIFIELD. Yes.

Dr. GRAVES. We have a large amount of fission activity and induced activity. He was restricting his comment to that. He said that of that, 25 percent in his example was deposited locally, and 75 percent went to the stratosphere. This will change depending quite a bit on how you detonate the device itself. It will change. In his particular example that is how he estimated.

Representative HOLIFIELD. The fact that 75 percent went into the stratosphere did not necessarily mean we were rid of that, because there is a factor of return to the earth, is there not, over a period of years?

Dr. GRAVES. Yes.

Representative HOLIFIELD. Eventually you would get 100 percent of the radioactivity, although your first part would decay.

Dr. GRAVES. You gain a lot if you can put it up into the stratosphere and let it stay up say 100 years. Instead of talking about 820,000 megacuries, you are talking about 0.00006 megacuries. That is a difference. If it is going to decay, let us let it decay 100 miles up.

Representative HOLIFIELD. Has it not been said that it will return in a period of 10 years?

Dr. GRAVES. That is right.

Representative HOLIFIELD. So we cannot talk about 100 years or 1,000 years; we must talk about 10 years.

Dr. GRAVES. Exactly. That is the reason strontium's 28-year half-life is important. If it were a half-life of 1 year, we would not worry about it. It has a half-life long compared to the time it stays in the stratosphere. Hence, still a lot of it is left when it comes down.

Representative HOLIFIELD. So you can say that most of the strontium 90 that goes into the stratosphere would eventually return to the earth, although it would be diffused much greater than that in the local fallout, as you term it.

Dr. GRAVES. Yes.

Representative COLE. Mr. Chairman, I would like to inquire of Dr. Graves, if you are permitted to answer, whether nuclear radiation is a desirable element of a military weapon——

Dr. GRAVES. No one has told me I can't answer that, except I don't know the answer.

Representative COLE. A weapon is for the purpose of destruction. With a nuclear weapon, that is the dazzling light, the heat, the blast and radiation. Those are the four destructive parts of the weapon.

Dr. GRAVES. That is right.

Representative COLE. What I would like to know is whether you feel you can tell us that the radiation phase of a weapon is a desirable factor from a military standpoint?

Dr. GRAVES. I am not told I cannot answer that, but I just don't know the answer. It would seem to me this might also depend on the particular tactics or strategy that are under consideration.

I am not expert on military matters, but if you are interested in establishing a beachhead, you want to be sure you can use that beachhead, so you would not want to put so much activity on the beachhead that you cannot land and utilize it. It would depend on the circumstances of the use of the weapon.

Representative COLE. And whether the nuclear radiation phase is a desirable element would determine the nature of the radiation you seek to create.

Dr. GRAVES. The military situation would certainly be an important consideration.

Representative COLE. What I am thinking is that if nuclear radiation does not have an important military significance in weapons use, I should think that the tendency and your tests and weapons improvement would be to make these weapons as free of nuclear radiation as possible, or in other words, to make them as clean as possible.

Dr. GRAVES. The purpose of our weapons test is to try to find out what we can do with these weapons, such that if someone asks for a weapon which is clean, we will be able to say we know what we can do to satisfy that particular requirement, or if they ask for a weapon with this characteristic or that characteristic. Hence, the weapons test is to give us the knowledge on which we can make an appropriate design to satisfy that requirement.

Representative COLE. Make them either clean or dirty as the military requirements indicate.

Dr. GRAVES. Yes, sir.

Representative COLE. I would hope that some of the other witnesses from the military might discuss that later.

Representative VAN ZANDT. Is it not true that nuclear radiation is contaminating?

Dr. GRAVES. Yes.

Representative VAN ZANDT. Do we not have contaminating weapons in our stockpile at the present time?

Dr. GRAVES. Yes. You mean weapons that are fission. Sure.

Representative VAN ZANDT. Contaminating.

Dr. GRAVES. Yes.

Representative VAN ZANDT. It is common knowledge that military strategists will employ contamination, in the prosecution of a war. They seek to isolate an area through contamination. In addition they might contaminate water for the purpose of producing moisture that would be radioactive.

Dr. GRAVES. I am not an expert on military strategy or tactics so I am afraid I cannot help you.

Representative COLE. It may be true that all of our weapons contain contamination. The question is whether that contamination is in there deliberately or inevitably.

Dr. GRAVES. As I say, if the weapon is designed to make use of the fission process, then that contamination is there inevitably whether the military wants it or not. As I answered you, the object of our tests is to find out whether it must be in there inevitably so that if it should not be wanted, then we would know what to do about it.

Senator ANDERSON. Doctor, in order to clear up any question when you got mixed up with fission or fusion, and my question whether it would be fission along with fusion, the page proof of the booklet, The Effects of Nuclear Weapons, issued by the Atomic Energy Commission, at page 17 has this paragraph. It has been declassified. We have just determined that:

> In order to make the nuclear fusion reactions take place, temperatures of the order of a million degrees are necessary. The only known way in which such temperatures can be obtained on earth is by means of a fission explosion. Consequently, by combining a quantity of deuterium or a mixture with a fission bomb, it should be possible to initiate one or more of the thermonuclear fusion reactions given above. If these reactions accompanied by energy evolution can be propagated rapidly through the volume you have the hydrogen isotope or isotopes, a thermonuclear explosion may be realized.

Therefore, I hope I was not getting outside the properly declassified section when I asked you if, so far at least, we did not have to have a fission explosion in order to have the following fusion explosion.

Dr. GRAVES. I am sure that what we have said earlier was perfectly all right.

Senator ANDERSON. I think it was all right.

Representative HOLIFIELD. Therefore, the conclusion we can reach is that there is a dirty bomb and there is no such thing as a clean bomb, and I am using the word "clean" in the absolute sense and "dirty" in the absolute sense.

Dr. GRAVES. There are dirtier bombs, and some that are less dirty.

Representative COLE. That is correct. It is not a question of a clean bomb versus a dirty bomb. There are varying shades of gray and white in between. It is not one or the other, is it?

Dr. GRAVES. No, sir.

Representative VAN ZANDT. Doctor, can this clean or dirty state be produced in the way you use the weapon?

Dr. GRAVES. Why don't I get into that discussion now? (See p. 99.)

This is the picture of the type of situation which results from a surface burst. In a surface burst of an atomic weapon or a nuclear detonation of any sort, there are two effects that should be mentioned. In the first place, the neutrons that escape from the detonation can strike the ground and hence produce induced activities. In the second place, large amounts of dirt will be mixed up with the cloud, radioactive particles will be plated out on these particles, and hence will tend to fall out more rapidly since these dirt particles will be heavy. So we have, then, here a typical mushroom. It will be very dirty. It will look dirty. You will have nearby fallout of the very heavy particles. At somewhat greater distances we will have fallout of the somewhat lighter particles. Then at very great distances, we will have fallout of the very fine particles.

If this is a relatively small device, very little of the activity will go up into the stratosphere. There is a stable layer in the atmosphere. Again this can be talked about more authoritatively by some of the other people who are present who will be speaking to you later, but there is a very stable layer in the atmosphere which tends to contain such explosions. For the normal small type of device the active material does not get above that, and hence it will all fall out close by, or at least on, say the first pass of the material around the world.

Whereas, from large bursts where the clouds go to very great altitudes, the activity can get up into the stratosphere and this may fall out as much as 10 years later, as Senator Anderson has pointed out.

The difference is that in this particular case we will have very much dirt mixed up with the mushroom. We will have very much close-in and near-out fallout and probably relatively less of the worldwide fallout.

Representative HOLIFIELD. Dr. Graves, before you leave that, you are assuming, of course, perfect test conditions when you make that statement.

Dr. GRAVES. No, sir, I am talking only about the case of a detonation which has occurred on ground. Whether it is a test condition or not.

Representative HOLIFIELD. But as far as the deposit of radioactivity is concerned, you are talking about what you would call safe weather conditions after this explosion, you would have a different situation, would you not?

Dr. GRAVES. I have not been discussing what would happen if you had rainfall or snowfall or that sort of thing, that is right.

Representative HOLIFIELD. That is why you are so careful in postponing your tests, in order to be sure that you have an element of as much certainty as possible with regard to weather conditions.

Dr. GRAVES. Yes.

Representative HOLIFIELD. So that you can get the maximum of protection.

Dr. GRAVES. In the case of testing weapons we try to avoid a situation where the device is detonated on the ground because we don't want to have this very heavy local fallout. We would like to avoid this situation if we can. We try therefore to use towers and make them as high as we can, or we use air bursts as in this chart, or we use balloons for holding the device up. All of this is to avoid getting this mixture of dirt into the cloud itself. (See p. 99.)

Representative HOLIFIELD. It was the purpose of my question to allow you to explain that point.

Representative VAN ZANDT. To take it one step further, suppose that the bomb was detonated under adverse conditions that included a lot of precipitation, what effect would it then have on the fallout?

Dr. GRAVES. Depending on where the precipitation was. Suppose there were a lot of precipitation right at the mushroom, instead of dirt, you would have globules of water which would fall fast. Hence you bring the fallout down faster.

Representative VAN ZANDT. In other words, you add moisture to the particle and make it heavier, and it falls to earth much quicker.

Dr. GRAVES. Exactly. In the case of an air burst, we detonate it high up in the air, and we have two effects. In the first place, there

is relatively little dirt mixed into the cloud and hence there is very little local fallout, very little at the intermediate distances. Practically all of it is spread around over great distances.

In the second pace, since the detonation occurs high up in the air, very few of the neutrons will be subject to capture by chlorine and sodium, calcium or silicon, so that there will be very little induced activity. Most of the activity will be in the form of fission particles and carbon-14 produced by capture of the neutrons in the air.

Then one should realize that there is a possibility of difference here. If you want somehow or another to avoid worldwide fallout the best way to do it is to do it as a surface or subsurface burst. For example, if for some reason we wanted to do our best to avoid fallout over the whole earth, this does it, because this puts most of it down locally. If we want to avoid local fallout, we do it high in the air.

Representative COLE. Dr. Graves, the record does not show which is this and which is that.

Dr. GRAVES. I am sorry. If we want to avoid local fallout and emphasize worldwide fallout, we do it by means of an air burst, the higher burst. If we want somehow to minimize worldwide fallout and maximize local fallout, then we do it by means of a surface burst or a subsurface burst.

Representative HOLIFIELD. That would be in the small kiloton range, would it not?

Dr. GRAVES. It could be either.

Representative HOLIFIELD. If you are going to the megaton range with the fireball touching the earth and with the height of the mushroom cloud, do you not defeat your purpose?

Dr. GRAVES. I am not saying what the purpose is.

Representative HOLIFIELD. I was thinking of a military purpose. The purpose of either having fallout locally or worldwide.

Dr. GRAVES. If we have a megaton weapon to detonate for some reason, if we want to minimize worldwide fallout we must maximize local fallout. Hence we will do it by some such system as this—get as much dirt mixed up in the cloud as we possibly can. If we want to minimize local fallout, no matter if it is a megaton or not, then we go to the air burst because then we minimize the amount of dirt mixed up in the cloud.

The subwater or the underground shots just make this statement more so. If we really want to maximize local fallout, then we detonate these things so deep underground or underwater that nothing goes in the atmosphere, and then it is all local fallout and no worldwide fallout. So if we go from a high air burst down to a case where the fireball touches the ground, and then to where the fireball is on the ground, and then to where it is away below the ground, we are essentially going from a case where there is almost no local fallout, where there is more and more and more local fallout, until finally it is all local fallout.

Essentially it is not fallout at all. It is underground where it stays.

Representative COLE. If that is so, Doctor, if local contamination is a desirable objective of our military, could not that be accomplished by regulating the place where the explosion occurs, rather than to have that contamination contained within the weapon itself?

Dr. GRAVES. All of this is assuming that there is contamination in the weapon. If there is no contaminating material in the weapon, then we won't have fallout anywhere.

Representative COLE. It is impossible to have an absence of contamination in the weapon?

Dr. GRAVES. Exactly.

Representative COLE. A while ago I asked to what extent nuclear radiation within the weapon itself was a desirable military objective. You said it would depend on the local conditions as to whether they wanted to contaminate an area. Now my question is, Cannot that local contamination be accomplished by regulating the height or place where the weapon explodes, rather than having the nuclear radiation contained in the weapon itself?

Dr. GRAVES. The answer is "Yes."

Representative COLE. If that is so, why is not in theory at least the goal of the military to achieve a weapon as free of nuclear radiation as possible and still obtain the blast and heat effect?

Dr. GRAVES. That is the point I was trying to make. If you have a military situation in which you want to contaminate a region very badly, you can't do it by taking a weapon with very little radioactivity in it and detonate it in any way to put fallout down. You have to have the fission products there in order to contaminate the region. Am I misunderstanding you?

Representative COLE. You were not misunderstanding me. I am afraid I am not completely understanding you.

Dr. GRAVES. We have agreed that we cannot produce an absolutely clean weapon. This I think, is clear. On the other hand, there are degrees of cleanliness. If you want to contaminate an area, then let us not pick the lesser degree of cleanliness and try to get activity which is not in the weapon itself.

Representative COLE. In order to have local contamination you must have fissionable products in the weapon itself.

Dr. GRAVES. That is right.

Representative VAN ZANDT. Dr. Graves, earlier this afternoon you said that an air burst at a certain altitude was found to be most effective. Were these conditions that you are now describing taken into consideration in arriving at that conclusion?

Dr. GRAVES. Yes. I said that the height of burst depends on the effect you are trying to produce. If you want to produce the maximum local fallout, then clearly the best place to do it is at or below the surface, or somewhere along in there. If the effect you are trying to produce is the maximum amount of worldwide fallout then the best thing to do is to do it high up in the air.

Chairman DURHAM. You would eliminate most of it by going deep enough in having the explosion?

Dr. GRAVES. If you go deep enough you will contaminate everything right where the explosion occurred. It might be pretty deep for a pretty big weapon, but that is certainly correct.

Representative HOLIFIELD. Of course, this does not take into consideration the strategy or the policy of the military in using these weapons, nor does it take into consideration the policy of an enemy nation in attacking us.

Dr. GRAVES. That is right.

Representative HOLIFIELD. We have no guaranty that an enemy nation will be considerate enough to handle this in a way which will do the least damage, do we?

Dr. GRAVES. No, sir.

Mr. Chairman, I have nothing further that I would like to stress particularly. As I say, I am very happy to have a chance to appear before you and if you have additional questions, I will be glad to answer them.

Representative HOLIFIELD. We appreciate your presentation, Dr. Graves. Will you be with us for the rest of the day in case there are additional questions?

Dr. GRAVES. I would be happy to stay.

Representative HOLIFIELD. Is it according to your schedule to stay? We are not asking you to stay, because we know the important work you are doing.

Dr. GRAVES. No, sir; I have all day today.

Senator HICKENLOOPER. At least while I have been in the meetings, Dr. Graves, there has not been any discussion or comparison of the impact of cosmic rays as compared to other radiating activity or any radiation which might come in from outer space, and how the intensity increases or decreases on that.

Representative HOLIFIELD. That is scheduled for later.

Senator HICKENLOOPER. That is fine. I did not know whether it was scheduled to be discussed.

Representative HOLIFIELD. Mr. Cole.

Representative COLE. Mr. Chairman, I am very hesitant to ask Dr. Graves to continue longer, but since Dr. Graves has been in charge of our weapons tests both in the Pacific and continental United States for the past 6 years or since he is here, it seems to me that it would be of public interest to hear from him the procedures which he and those in charge of the tests followed in order to minimize the consequences of the tests, if he can do so within a few minutes. It is a rather large order, because I am somewhat familiar with the extent of your efforts. But I would like at least to give you an opportunity of telling the public of just what you and your staff do in having the tests occur under conditions which will cause the least damage.

Dr. GRAVES. May I start with the statement of the work which has gone into planning the present series, Mr. Cole, because in my opinion the main safeguards that are introduced into the tests of weapons occur during the planning stages.

In planning the present series, we were faced with the necessity for testing a relatively large number of devices, larger than we had tested before. Hence our planning was conditioned on that particular basis. Since we had to test more devices, we had to be even more careful in this set of tests than we have been in the past. As a result, we went back to the individual laboratories and to the Department of Defense, and told them that some of the tests that they were requiring to be done seemed to us to make the overall operation difficult and asked that they consider their particular requirements to see if somehow or other they could not raise the height of burst, change from towers to balloons, decrease the planned yield, or do such things.

In fact, we also suggested in several cases that the tests be combined so that the data could be obtained from a single test or a single detonation, rather than from two.

We also devised a new method of determining the relative hazards of a particular test by estimating the number of megacuries—the numbers that I placed on the board over there—which would be deposited locally. So that if we have a case where a hundred megacuries is going to be deposited locally, we can be sure that test will be less dangerous than one in which two hundred megacuries would be deposited.

In this way we were able to compare one test with another. We could decide which particular test we should worry about. We could decide whether this series was going in fact to be worse than the next series or the past series or not.

Once we have finally come up with a plan whereby the total amount of fallout is minimized, then we have to come to face with problem of carrying on the tests such that even the fallout that does occur will not hurt anybody. In order to do this, we have assembled in Nevada as competent a meteorological group as one can find anywhere. This meteorological group tells us long in advance what the weather will be like, such that we can control where the fallout will occur.

The test area is in the midst of a bombing range which consists of very many square miles where there is no one. If we can arrange things such that the fallout occurs in this bombing range, then we will be sure of not hurting anyone. In order to guarantee that it will fall in the bombing range, we have to know what the weather is going to be like. The postponements that have occurred for the last 10 days or so have all been due to 2 facts. In the first place, we have had unusual high winds. We have had a jet stream coming through which could carry the material to great distances, and that we do not like. We would rather have the fallout occur on our bombing range. In the second place, we have had a lot of precipitation. I know those of you who have been out there with us realize that we have been on a desert, but you may be surprised to find out that a few days ago our meteorologists told us there would be scattered showers in the region in the desert. We said let us not shoot while we have showers. I went into town that night to tell the newspaper people why we had this postponement, and I almost drowned getting back out. There was a flood. The highway was covered with water, and we had 6 inches of water in our ditches in the desert.

The next day they told us we might have some snow flurries. We had snow out on the desert. All these conditions are not feasible for tests because they sweep down the radiation and put it on the ground in regions that we can't control.

Consequently, I would like to give a very considerable hand to this group of meteorologists who we have out there who may make us mad because they make us postpone, but they keep us out of trouble. They tell us the weather with great accuracy and permit us to be sure that the weather will not give us a fallout situation that we would not like.

I am often asked the question, why is it that we don't do all of these shots by high airburst. We discussed here the possibility of minimizing local fallout by using high airbursts. The conditions of testing are largely the conditions pertinent to the information we want to

get. We are not interested in producing there, information such that if someone says to make a weapon, then the laboratories will have the information they need to make that weapon. It turns out that there are experiments that must be performed to get some information in which the position of the device must be known with extremely great accuracy.

I may say that we have an experiment proceeding in which the position of the device to better than a half inch is required. Clearly this sort of accuracy is impossible from an air burst. It is even impossible with a device suspended from a balloon.

There are other cases where we don't care where the device is to a half mile or something of that sort. We just don't care. In such cases, I think we would be very wrong if we did not arrange somehow or other to detonate these devices high up in the air by an air burst.

So what we do is to then say our laboratories have certain requirements. They require us to test certain devices. They require us to get certain information from those devices. Our job in Nevada and in the Pacific is to devise a plan whereby these tests can be made and these experiments done safely.

Representative COLE. There is only one other question. What has been your experience with respect to radiation damage that has been the consequence of tests during the time you have been Director, limiting it to the tests in Nevada.

Dr. GRAVES. Again a part of the planning activities before this last series of tests was to accumulate all of the known data, all of the data from previous tests, to accumulate all of the measurements which have been made, and to interpret these as best we could into the total dose in all of the communities around the Nevada test site. These doses do not mean that the people in these communities got those doses, but it does mean that a certain fence post would have been exposed to that particular dose, and if someone stayed near that fence post he would have gotten that dose.

We looked at it and the best we were able to determine is that in the region which is now inhabited, the highest accumulated dose would have been something like 4.5 roentgens in the 6 years we have been there. This is something less than 1 roentgen per year. I am speaking from memory so don't hold me too firmly. I think there was one place with 4.3 roentgens. I don't remember now the name of the town. There was one with 4 roentgens. But the great majority were less than 4 roentgens. I am eliminating one place known as Riverside Cabins, where no one is actually living now. The people who were living there were living there for 1 year, as I recall it. The infinite dose to those cabins if somebody had lived there forever would have been something like 7 roentgens. This was the only place that I know of that received more than this 4.3 I have discussed.

Representative HOLIFIELD. Thank you very much, Dr. Graves. We appreciate your testimony.

Our next witness is Dr. Frank Shelton, of the Armed Forces special weapons project.

Dr. Shelton, will you come forward and take the right hand chair.

STATEMENT OF DR. FRANK SHELTON, TECHNICAL DIRECTOR, ARMED FORCES SPECIAL WEAPONS PROJECT [4]

Dr. SHELTON. The material presented to you by Dr. Graves was coordinated with me, and I concur in the statements that he has made to you. To a large extent I feel that the material was gathered and in part reflects the material in The Effects of Nuclear Weapons, the publication which some of you have before you. That being the case, the material as presented I would consider representing an official Department of Defense and Atomic Energy Commission position regarding the accuracy of the material.

I believe that is about all I have to say.

Representative HOLIFIELD. Dr. Shelton, you know that this page proof was only delivered to us I think late Friday, and we have not had a chance to even begin to read it.

Dr. SHELTON. Yes. I was informed this morning that the AEC had made copies available last week.

Representative HOLIFIELD. Therefore, we are not in a position at this time to question you on that particular book. You have no other statement to make?

Dr. SHELTON. I might mention a few words about the organization which I represent. The Armed Forces special weapons project, among other people, helped to prepare the book you have before you. It is the organization within the Department of Defense which would have primary responsibility during the weapons tests to obtain weapons effects data, principally for the Department of Defense. However, we have obtained a good deal of material at the request of the Atomic Energy Commission. We have, for example, been the organization which would gather together the capability of the country to measure the fallout from such an operation as the last Pacific one.

Representative HOLIFIELD. The only thing I can say then, unless there are some questions, is that the staff and the members will have to look at this before we present any questions to you. It is possible that we will call you back later.

Dr. SHELTON. Yes. What I had in mind saying was that I thought Dr. Graves had worked up a very complete presentation for you. I thought it would be somewhat redundant for me to elaborate further. Finally, that much of the material that he presented to you is material which we have already coordinated on and is the official position on the part of the Department of Defense.

Chairman DURHAM. Doctor, give us the size of the composition of your organization, and how you operate. Do you operate in connection with the Los Alamos Laboratories and all the rest of the laboratories throughout the country?

Dr. SHELTON. The Armed Forces special weapons project, as I said, is an agency of the Department of Defense. Essentially we work for the three services, the Army, the Navy and the Air Force, and it is our job to obtain the effects data that they require in the employment

---

[4] Technical director of the Armed Forces special weapons project. He has been active in the atomic-energy field since 1952. During the spring of 1955, he served as technical adviser to the Military Effects Test Group at Operation Teapot, and in 1953 participated in Upshot-Knothole. Dr. Shelton was born in 1924. He received his bachelor of science, masters, and doctor of philosophy, all in physics, from the California Institute of Technology. Prior to joining the Armed Forces special weapons project, Dr. Shelton was with the Sandia Corp. in the weapons effects field. (Submitted by Department of Defense.)

or anticipated employment of nuclear weapons. To get that information we must participate on the full-scale weapons tests. To do the job, we have called upon many of the Government laboratories, and a number of the civilian laboratories to actually go into the field and to obtain the data.

The Armed Forces special weapons project would then have as its job the assembling of that group of people. We actually coordinate that effort, and guide those people in the field to obtain the required data.

Chairman DURHAM. You tell the weapons division at Los Alamos or Livermore the type of weapons you want?

Dr. SHELTON. It is usually not that way. More nearly the case is that they are detonating a particular type of weapon in the process of development. In a more normal case, we would be aware of that type of weapon and need for information from that type of weapon. We do not tell them the type of weapon.

Chairman DURHAM. You suggest through the military channels what type of weapon you desire. Isn't that the procedure. That is, for whatever size mission?

Dr. SHELTON. Yes, sir. There are broad characteristics required by the Department of Defense in the weapons which eventually would be stockpiled.

Chairman DURHAM. What part do you take in evaluating the tests after they have already been completed?

Dr. SHELTON. When a test has been completed and we have obtained the data in the field, AFSWP continues to monitor the agencies that have taken that data, and in the final production of the reports. One of our largest functions is production of final test reports, on the effects, and not the develcpment of weapons.

Chairman DURHAM. Do you go into the hazard at all of the radiation fallout or does that rest entirely in the laboratories?

Dr. SHELTON. Our large participation in fallout has been pretty well confined to the local fallout. For instance, in the last Pacific tests, we did document many thousands of square miles of the ocean. It was the AFSWP that documented the local fallout in the last Pacific tests.

Chairman DURHAM. Do you have any contact with NATO or the Far Eastern organization SEATO?

Dr. SHELTON. In addition to obtaining the information on weapons effects, we do transmit to the services that type of information in various publications. Those various publications are distributed to the American portion of NATO. Of course, there is the classification problem again. Typically one of our best known publications is one called Capabilities of Atomic Weapons. This is a compilation of the effects as we best know them. That is distributed to all of the Armed Forces of the United States.

Representative HOLIFIELD. Dr. Shelton, do you have or can you present to the committee an unclassified list of the tests which we have held and an estimate of the radioactive mission of those tests? Is that permitted?

Dr. SHELTON. You are asking for a compilation of the tests in chronological order, and you are asking for the amount of radiation produced on those tests?

Representative HOLIFIELD. I am asking you if that can be given to the committee on an unclassified basis or not?

Dr. SHELTON. I have discussed this subject, prior to coming here, with members of the AEC. We feel that we could not do that. We could do it in a closed session.

Representative HOLIFIELD. I understand that.

Dr. SHELTON. We feel that it would reveal information of a sensitive nature.

Representative HOLIFIELD. In this book which I have not had a chance to read yet, you do not go beyond the description of explosion of one weapon, let us say. There is no extrapolation of what would occur in a war if 100 weapons of a megaton or 5 megatons each were exploded on the United States?

Dr. SHELTON. What you have said is essentially correct. The phenomena as presented are over varying yields, but presented as one shot at a time and the effects that you can expect. The only effect, of course, that would be additive in a real large sense would be the fallout. In the normal employment of weapons one would not typically overkill his target by repeatedly blasting weapons in the same spot. We did not treat the fallout except on a one-shot basis.

Representative HOLIFIELD. I notice on page 419, you have a description of a 1-megaton surface burst with a pattern of radioactivity, and the number of miles involved, the number of hours involved for downwind distribution at the rate of 15 miles per hour wind. It would be possible, by extrapolation, however, to take that particular description and apply it to 100 or 200 weapons if you know the meteorological conditions as of a certain time.

Dr. SHELTON. What you have said is essentially correct. Although the chart given is for the dose rate at 1 hour, for a 1-megaton weapon, one finds the prescriptions given here, the mechanics of getting the same pattern for any other yields. We were not so explicit in giving you the pattern for other winds. As you saw, it was a uniform 15-mile-per-hour wind at all altitudes. I believe Dr. Kellogg, who is to follow us, will give you varying winds, but we feel that the fundamental areas involved are represented by the chart and the prescriptions given for other yields.

Representative HOLIFIELD. As a matter of policy, you do not believe that we should keep from the American people the effects of atomic or hydrogen weapons, do you?

Dr. SHELTON. Indeed not, sir. We have gone out of our way, for instance, in presenting the book that you are talking about and go just as far as we could go. In fact, many of the statements in the book required careful consideration of classification and the final determination that in the interest of the public that was the proper thing to do. We have withheld perhaps only a small percentage of all that is now known about nuclear weapons which is in the sensitive area relating to design of weapons.

Representative HOLIFIELD. You are presenting this book for the committee's action if they so desire of including it in the record, are you not?

Dr. SHELTON. The advanced copies of The Effects of Nuclear Weapons were distributed to the committee by the AEC. Any portions of that book for the record are perfectly all right. I noticed that the book

as I have it here does not have the preface, and I believe that would have explained the role of AFSWP in the preparation of the book. There is a preface and acknowledgment that I presume will go into the final publication.

Chairman DURHAM. Your division prepared this entirely?

Dr. SHELTON. Our division prepared this book in cooperation with Dr. Glasstone, and with the cooperation of the Atomic Energy Commission. We were asked to help prepare the book, and we did.

Representative HOLIFIELD. General Starbird, do you wish to add anything to what Dr. Shelton has given to us today?

STATEMENT OF GEN. ALFRED D. STARBIRD, DIRECTOR, DIVISION OF MILITARY APPLICATION, ATOMIC ENERGY COMMISSION [5]

General STARBIRD. I have nothing specific to add, sir.

Representative HOLIFIELD. You have not prepared formal testimony?

General STARBIRD. I had prepared, Mr. Chairman, some testimony originally when I thought I was to be the first witness. That testimony has been made available to you. It is entitled, "Testimony Before the Joint Committee on Atomic Energy on the Production of Radiation and Radioactivity From Nuclear Weapons." Knowing that Dr. Graves would be available, I consulted with him. I do know that the information contained in the statement that I mentioned has Dr. Graves' concurrence. I find that he has covered verbally everything that is in the statement and in somewhat more elaboration. I would like to request, therefore, that the statement be added to the record.

Representative HOLIFIELD. Thank you. It will be accepted without opposition.

(The statement referred to follows:)

TESTIMONY BEFORE THE JOINT COMMITTEE ON ATOMIC ENERGY ON THE PRODUCTION OF RADIATION AND RADIOACTIVITY FROM NUCLEAR WEAPONS

TOPIC V

1. In this, the 5th topic of the hearing before your committee, we have been asked to cover the Production of Radiation and Radioactivity with Nuclear Weapons. From earlier witnesses you have received general background information on radioactivity and its effect, together with a description of the two basic nuclear processes (fission and fusion). For this topic we have been asked to discuss the nuclear process employed in weapons, to describe the several different physical effects which the explosion of a nuclear weapon would give, and to discuss briefly the division of radiation energy which would result from various conditions of firing. We have prepared a written statement covering these matters and I shall follow closely that statement in my oral presentation.

Description of nuclear weapons

2. An explosion is the release of a large quantity of energy in a short interval of time and within a limited space. The release of this energy is accompanied by a very great increase in temperature so that the products of the explosion become extremely hot gases. The expansion of the air heated by a nuclear

[5] Date and place of birth: April 28, 1912; Fort Sill, Okla. Education: Bachelor of arts, U. S. Military Academy, 1933; civil engineering, Princeton Engineering College, 1937. Dak., 1950; Secretariat, SHAPE, Paris, France, 1950–53; Office, Chief of Engineers, 1953–55; Director, Division of Military Application, AEC, 1955. (Submitted by the Atomic Energy Commission.)

detonation causes the formation of a blast wave. When the head of the wave (the shock front) passes a given point it results in an abrupt rise in pressure causing some of the destructive effects of the explosive.

3. The nuclear bomb is similar to the more conventional high explosive bomb in that a portion of its destructive action is due to the blast or shock discussed above. However, apart from the fact that the nuclear bomb can be many thousands of times more powerful than the largest TNT bomb, there are other more basic differences. Firstly, a fairly large portion of the energy from a nuclear explosion is emitted in the form of light and heat. This emission is referred to generally as the "thermal radiation." It can cause fires or skin burns at considerable distances. Secondly, the explosion is accompanied by highly penetrating, but invisible, rays called the "initial nuclear radiation." Finally, the substances remaining after the nuclear explosion are in large part radioactive, emitting similar nuclear radiations over an extended period of time. This later radiation, arbitrarily taken as that which occurs later than 1 minute after the bomb's initiation, is commonly referred to as the "residual nuclear radioactivity."

4. Earlier nuclear weapons made use only of the fission process in the achieving of this high energy nuclear detonation. In this process neutrons are caused to enter the fissionable nuclei of atoms of either uranium or plutonium. Under certain prerequisite conditions the fissionable material is split (or fissioned) into fission products by an almost instantaneous chain reaction. During the fissioning, great quantities of energy are released. Neutrons and gamma rays escape from the fissioning material and bombard surrounding elements, forming some radioactive isotopes. The fission products which result from the explosion constitute a very complex mixture. This mixture may consist of about 170 different types of fission debris which are isotopic forms of some 35 different chemical elements. (See chart I.) This fission debris initially is highly radioactive and decays over a period of time by the emission of beta particles and gamma rays. From each kiloton of fission yield approximately one-tenth of 1 pound of radioactive fission products can be expected to occur. At 1 minute after the explosion, when the residual nuclear radiation has been postulated as beginning, the radioactivity from the fission products of a kiloton of fission energy yield is comparable to that of some 100,000 tons of radium. The radioactivity decays rapidly. For example, there are given below the estimated total gamma activities of the fission products from a nominal atomic bomb, expressed in megacuries, at various times after the detonation.

Total gamma activity of fission products in megacuries

Time:	*Activity*	Time—Continued	*Activity*
1 minute	820,000	1 month	2.3
1 hour	6,000	1 year	.11
1 day	133	10 years	.008
1 week	13	100 years	.0006

5. Later, means were found of using the fusion process to secure weapons of higher yield than were practical from the purely fission designs. You will remember that a fusion process is the uniting or fusing of very light elements to form heavier elements and that great quantities of energy are given off in the process. To initiate a fusion process tremendous heat is required. The term "thermonuclear" results from the fact that such weapons use heat to maintain the nuclear reaction. In contrast to fission, no fission product radioactivity results directly from fusion. Fusion, however, is accompanied by the escape of neutrons, some of extremely high energies, and these can induce radioactivity in materials with which they come in contact. Naturally, too, in a thermonuclear weapon the fission portion of the reaction forms radioactive debris in the same manner as in a purely fission weapon.

6. The partition of energy from a nuclear explosion as between blast and shock, thermal radiation and nuclear radiation varies somewhat with the design of the device and with its condition of firing. As a general approximation nevertheless, the division can be considered as that shown by chart II. The chart portrays specifically the result which could be expected from the detonation of a device of yield of 1 megaton, fired within the earth's atmosphere, but at such altitude that comparatively little extraneous material from outside of the device is available to be made radioactive by escaping neutrons (as for example, if fired at a few thousands of feet in the air).

7. You will note that in this case some 50 percent of the energy would be released as blast or shock, some 35 percent would occur as thermal radiation (heat or light), while some 15 percent would be in the form of nuclear radiation. Of

this 15 percent, roughly one-third would be "initial radiation" occurring within 1 minute after firing, while two-thirds would be "residual radiation." The highest intensity of this residual radiation naturally would occur during the seconds immediately after the first minute. It would decay rapidly thereafter but some small residual radioactivity could be expected for many years or even thousands of years after the detonation. (See table in paragraph IV.)

8. The 50 percent of the energy translated into blast or shock would have effects quite similar to those to be expected from a high explosive detonation. (See chart III.) These would consist of a shock front (the head of the blast wave), a later region of high and low pressures behind the shock front, and a violent wind flow. This latter would initially be in the direction outward away from the explosion, but later in a reverse direction. The damage caused by the shock or blast would be, of course, a function of the weapon's yield, of distance from the firing and of the strength of the receiver. In the case of a typical air burst, the distance to which a given overpressure (or blast effect) extends varies generally as the cube root of the yield. The term "generally" is used for the reason that there are other factors such as reflected or refracted shock waves and pressures which under many conditions can reinforce or interfere with one another in such manner as to change materially the blast effect at a given point. As an indication of the order or magnitude of the effect one might expect from this phenomenon the burst of a 20-kiloton weapon at an altitude of several hundred feet could be expected to destroy beyond economical repair a multistory reinforced concrete building at distances up to one-half mile. On the other hand, a 1-megaton burst fired under comparable conditions could be expected to give similar damage to the reinforced concrete structure at distances up to 2 miles. Although large pressure differences result in injury to the human body, persons are more likely to be injured by flying objects, crushed or buried under buildings, or thrown against fixed structures than to be injured directly by wave overpressures.

9. The one-third of the weapon's energy emerging in the form of thermal radiation is contained initially in a relatively small volume of incandescent gases resulting from the vaporization of components of the device and of the adjacent atmospheric or other materials. (See chart IV.) This intensely hot spherical mass termed the "fireball" is visible for a perceptible period of time until the thermal radiation has been dispersed over such volume that visible light is no longer emitted. The initial temperature of the fireball is of the order of several million degrees and the thermal radiation covers a broad spectrum of wavelengths and includes ultraviolet, visible, and infrared. These radiations travel outward at tremendous speeds. The extent of injury or damage to a person or material resultant from thermal radiation is a function mainly of total energy received, but secondarily of the rate of absorption. From a given weapon, or from weapons of comparable energy yield, the intensity of thermal radiation received is a function primarily of distance from the burst. The amount varies inversely as the square of the distance, provided there were no attenuation by the atmosphere. The period over which thermal energy is given off from an explosion increases with the yield—that from a kiloton device being limited to a few tenths of a second but for a megaton device the period may extend to several seconds. A 20-kiloton burst could be expected to ignite combustible house materials at ranges up to 2 miles, while a 1-megaton burst could have similar effect up to 10 miles. The 20-kiloton burst could cause first degree burns to exposed skin surfaces at ranges of 3 miles, while a megaton burst could cause similar burns at 14 miles. Adverse weather conditions can vary the distance at which these effects occur.

Nature of the nuclear radiation from a weapon

10. The 15 percent of the weapon's energy which becomes nuclear radiation is the result of several actions and interactions. Some of these, of course, occur immediately after firing while others are much later in the chain. To name the primary of these actions (chart V):

(*a*) Firstly, the initial fission or thermonuclear reactions emit high gamma and neutron fluxes.

(*b*) Secondly, radioactive debris products result from the fissioned atoms. The radioactive debris products condense into particles of various sizes and may fallout locally or at a distance depending upon their size and the altitude from which they fall, as well as meteorlogical conditions. The individual radioactive isotopes regain their nuclear stability by giving off beta particles, which in a large fraction of the cases is accompanied by emission of gamma radiation. The average time for the atoms of a particular isotope

to reach stability varies from a fraction of a second to thousands of years.

(c) Thirdly, neutrons contribute to the residual radiation by inducing activity in various elements of the materials in the bomb, atmosphere or in substances which may be in the explosion environment.

11. Essentially all neutrons escaping a bomb are released from the fission or fusion reaction of the bomb's nuclear material. They emerge almost immediately after initiation of the firing. Though they represent only a very small portion of the total energy yield of the explosion they can possess a sizable kinetic energy. They can penetrate relatively long distances through the atmosphere (of the order of several thousand feet near sea level) and can induce radioactivity in the atoms they encounter. The distance at which the neutrons from a nuclear explosion can in themselves constitute a hazard is a function of the type of reaction, of the size of the explosion, and of the materials surrounding the bomb. From thermonuclear reactions, neutrons of higher energy are released than from the fission process. On the other hand, the number of neutrons escaping to travel to great distances depends on the thickness and type of material which surrounds the nuclear constituents of the bomb.

12. Gamma radiation, like neutrons, is released in large quantities from the initial explosive mass and can pentrate considerable distances through the air. Further, additional quantities of gamma radiation can result from the interaction of escaping neutrons with particles they encounter, and from the subsequent decay of radioactive elements throughout their life. A sizable portion of the residual radiation from a nuclear explosion is released ultimately as gamma radiation. This release is of decreasing intensity with time, but can continue for many years.

13. Two other forms of residual radioactivity alpha and beta particles, are found normally in bomb debris. The alpha particles are of very short range and result only from the unfissioned portion of the original fissionable material. If the fissionable material is available in sufficient quantity and is taken internally into the body, the alpha radiation from it could (with long residence in the body) cause extensive damage. However, for various reasons which will be discussed under a later topic, this unfissioned material is generally less of a hazard than some of the fission products. Beta particles (electrons) have a limited range. Depending upon the initial energy, the range may be only a few centimeters in atmosphere at sea level. Such particles result from the decay of fission products. They can constitute a hazard, but only when deposited on the body's surface or internally.

Type of weapon bursts and their effect on radioactivity

14. The portion of a bomb's energy that emerges as radioactivity (as contrasted to that portion which emerges as blast or thermal) is a function primarily of bomb design. Naturally, if the fission yield is high in contrast with the fusion a greater relative quantity of fission debris products will result. Naturally, too, the higher the energy of the escaping neutrons and the greater the amount of material close to the explosion, the greater will be the induced activity.

15. The conditions of the firing of the weapon, however, can have an important effect both on the amount of total residual nuclear activity and importantly on the distance at which that activity can be felt. In this connection, I shall mention briefly and generally the changes in residual radioactivity distribution which could result from weapons or devices fired on the earth's surface; at several hundreds or several thousands of feet in the air; underground; or underwater.

(a) In the case of a surface or near surface burst (chart VI), a large quantity of the surface material could be drawn up into the fireball to be mixed there with the radioactive fission products while those products are still in gaseous form. Escaping neutrons encountering this drawn up material could induce radioactivity therein. At the same time, however, when the cooling radioactive gases condense they would form in part larger particles which would trap (or scavenge) the material's residual radioactivity. These larger particles would fall out rapidly and relatively close to the firing point from such a burst, thus making local fallout heavy.

(b) In the case of an air burst at several hundred or several thousand feet altitude (chart VII) where the fireball does not touch the ground, the debris from the fission process would be unchanged in amount from that of a low altitude burst. However, the induced activity caused by the interaction on particles sucked into the fireball from the surface would be lacking. The total radioactive debris then would be less than in the case of the surface burst. The scavenging material from the earth's surface also would be lacking. The particles into which the debris condenses would generally be

smaller than in the case of a surface burst and would drift to the earth's surface at a distance from the firing.

(*c*) In the case of an underground or an underwater burst it is theoretically possible to place the detonation at such depth that little or no radioactivity would reach the atmosphere. Naturally, for such firings the induced activity would be relatively high, but would be confined in the earth or water along with the bomb's debris fragments. In the case of underwater shots, the movement of their residual radioactive particles is affected by ocean currents. In the case of underground burst, however, movement could only be through transfer of the surrounding material to the outside or by leaching. Great depths would be required to confine weapons of multikiloton or multimegaton yield if total initial radioactivity is to be confined.

Measurements and limitation on the data

16. In each of our several test series we have devoted a great deal of effort to the securing of information on the effects to be expected from nuclear weapons. Certain information can be readily secured and other is most difficult to measure or estimate.

17. We have available detailed information on the blast and shock effects to be expected from weapons of various sizes, on various type structures, under different conditions of firing, and different ranges. These data present rather precise estimates of what could be expected from a future detonation or detonations. The same is true, but to a somewhat lesser extent, with respect to thermal radiation.

18. With regard to nuclear radiation we have devoted intensive effort and with all means available to date to the securing of essential information. We can estimate with a fairly high degree of reliability the initial radiation which will result from a certain firing. With respect to residual radiation, because of the time over which it will occur and the many factors (including atmospheric) which have effect, the giving of precise forecasts is much more difficult. I shall not attempt to cover these factors, nor their reliability, in view of the fact that many of the later witnesses will give expert testimony in this regard.

Representative HOLIFIELD. Are there any questions of Dr. Shelton or General Starbird?

Representative COLE. Mr. Chairman, I should like to have either of the witnesses comment on the question which I propounded to Dr. Graves. I shall leave to them the realm of the classified or security information.

I would like to know to what extent internal nuclear radiation or induced radiation is an important factor in determining weapons development.

General STARBIRD. The radiation that is in the weapons basically that were discussed, sir, was inherent in the original design of weapons. It would be possible that that radiation could have some military advantage. But our major effort of our laboratories over a past period of several series has been to find ways and means of decreasing the contamination that would result from a nuclear detonation.

Representative COLE. Is it a fair conclusion, then, that your goal is to obtain a weapon with the greatest yield and the least amount of radiation, whether internal or induced?

General STARBIRD. That is one of our major goals, sir.

Representative COLE. Is it to any extent a goal to obtain a weapon with a minimum of blast and heat and a maximum of radiation?

General STARBIRD. I know of no such goal, sir.

Representative COLE. That is enough.

Chairman DURHAM. Your preference, of course, would be no radiation?

Representative COLE. If you can get the same blast.

General STARBIRD. To carry out the objective I mentioned, the fulfillment of that objective would be to get none.

Representative VAN ZANDT. Does a nuclear weapon offer a field commander the capability of contaminating an area with radiation?

General STARBIRD. As Dr. Graves mentioned, a greater amount of radioactivity can be placed locally. I think, sir, this would be the best answer. However, I cannot comment on whether that would be an objective.

Representative VAN ZANDT. Then radiation does play a part in the prosecution of a nuclear war.

General STARBIRD. It certainly plays a part, sir.

Representative HOLIFIELD. As a matter of fact, you cannot have a nuclear war as far as you know now without radiation, can you?

General STARBIRD. I know of no way.

Representative HOLIFIELD. Looking at this strictly from a military standpoint, why would you, without any assurance that the enemy is doing likewise, want to decrease one of the powerful elements of the weapon—there being 3 elements, 1 blast, 1 heat, and 1 radiation—looking at it strictly from a military standpoint. Why would you deny yourself one of those elements?

General STARBIRD. One would like to have weapons that he has the greatest amount of control over.

Representative HOLIFIELD. But if you did have a weapon where you had a maximum control over the factor of radioactivity would you have any assurance that a ruthless enemy would not take advantage of this other powerful element of the weapon in an onslaught against us?

General STARBIRD. I feel I am not really the one to answer that, sir. My field right now is in an assignment with the Atomic Energy Commission. To answer your point from a personal viewpoint, I don't know of anything that we could do to guarantee that the other man would do likewise.

Representative HOLIFIELD. Are there any questions of General Starbird?

Senator ANDERSON. Did I understand you a moment ago in answer to Congressman Cole's question to say that you were trying as far as possible to reduce the radiation in weapons?

General STARBIRD. This is an objective, sir, of the Commission's program, that is, to find ways and means of reducing the contamination from a weapon.

Senator ANDERSON. I am not talking about the Commission's program now. I am talking about the military program. Do I understand it to be your testimony that the military is now engaged in trying to reduce the radiation? If so, I would like to whisper to you here on the side the question that you can either comment on or not.

General STARBIRD. No, sir, I think I can comment. Certainly the military has indicated to us a great interest in weapons that have a lesser contamination for the yield involved.

Senator ANDERSON. I was not talking about interest. I was talking about program.

General STARBIRD. We are the ones, sir, as you know, who actually do the development work and the actual research for the production of the nuclear weapons. Generally to carry out an express requirement or expression of interest by the Department of Defense.

Senator ANDERSON. To whom can I direct a final question and see if it is classified?

General STARBIRD. Mr. Marshall is Director of Classification.

Representative VAN ZANDT. General, is it not true that in the employment of special weapons the field commander has to have a variety of them? He may call upon a weapon where he wants no contamination left after the burst, or he may employ a weapon where he wants to contaminate a great area. So it is up to you people to develop various types of weapons to give him the versatility he must have in the prosecution of a nuclear-type war. Am I correct in that assumption?

General STARBIRD. It is true that a versatility of weapons increases the strength of the military force, sir.

Senator ANDERSON. I have no further questions.

Representative HOLIFIELD. Thank you very much, gentlemen. As I said to Dr. Shelton, we will want to look at this book and possibly call you back later.

General STARBIRD. Thank you, sir.

Representative COLE. Would the Chair indulge me for just a moment in order that I may fill in a gap—not from these witnesses—when Dr. Graves said at the motel in Nevada the highest dosage was 7 point something roentgens.

Dr. GRAVES. That is correct.

Representative COLE. Tell us, since you are here, Doctor, what are the rules of the Commission with respect to safe dosages of workers in the Commission's laboratories, and so forth.

Dr. GRAVES. I have forgotten the title, but I think it is the American Commission for Radiation Protection, or something of that sort, originally stated that the workers in radioactivity could take one tenth of a roentgen per day forever without suffering injury. In the Commission laboratories it was determined that we should reduce that by roughly a factor of two and so it has been reduced to three-tenths of a roentgen per week.

In our test operations we have said that we will permit our people to take this three-tenths of a roentgen per week. However, they went for a quarter of a year, which would be 13 weeks, and hence our test criterion has been something like 3.9 roentgens per quarter or per period of 13 weeks. This means that our people in the test series we have tried to keep below 3.9 roentgens. We have not always done that. As a matter of fact, there have been a number of cases where people have gotten 3, or 4, or 5 times that much. For people offsite, we would like to do better than that. It is our feeling that if people are not willingly engaged in this activity, we should not ask them to take as much as we do. So we try to say that people offsite should not get more than 3.9 roentgens per year instead of per quarter. The present criterion is, I guess, 3.9 roentgens per series.

Representative COLE. I would like you to comment on the lethality of the 7 or so roentgens given to the motel.

Dr. GRAVES. The lethal dose is around 450 roentgens. This is very much less than that. Again this is not a subject on which I am an expert. So I don't want this to be taken as expert testimony in your record. To my knowledge, in order to be able to examine the blood or tissue or blood of someone and find out they have been exposed to radiation, the minimum dosage you can detect by some changes in the body you can see immediately is something like 20 or 25 roentgens. If it is less than 20 or 25 roentgens, there is no test we can make on an individual to show he has had radiation. If we get up above 20 or 25 roentgens, you begin to notice that there have been changes made in the blood. Some cells have become broken up or deformed in one way or another. You can detect some small changes above 25 roentgens. At about 75 roentgens or 100 roentgens a person would become ill, nauseated, and have some radiation sickness, and would recover, and presumably be all right. It is around 400 roentgens when you begin to find a few people die. Around 450 about half of the people would die, or something of that sort. So this 7 roentgens is considerably less than the amount that one can detect by any means that we know of for detecting radiation.

Representative COLE. Is it a fair conclusion, then, that the persons who may have been exposed to that dosage of 7 roentgens were not harmed in any way.

Dr. GRAVES. That is not a fair statement, because then you get me in trouble with people who are worried about long-term effects.

Representative HOLIFIELD. The Chair might say we are going into the pathology feature of this, and we have a list of distinguished witnesses that will testify on this point.

Dr. GRAVES. Yes. I want to be sure you understand I am not an expert in this field. I do not mind talking about it, but do not take my testimony as expert in that particular connection.

Representative VAN ZANDT. Mr. Chairman, may I ask this question. Doctor, how many roentgens did your body absorb in the Los Alamos accident?

Dr. GRAVES. I had about 200.

Representative COLE. From outward appearances you look rather healthy.

Dr. GRAVES. Thank you.

Representative COLE. At this time some several years later.

Dr. GRAVES. That was in 1946, so it has been 11 years. But this really is not important. You may have one person take 200 roentgens as I did and be perfectly happy for 10 years. But does it give me a greater probability of having cancer or does it give me a greater probability of this, that or the other, we just do not know. The danger is not that this will happen to you. The danger is that it is more likely to happen to you. Maybe the more likely is not very much more likely, but it is still more likely.

Representative VAN ZANDT. Doctor, how did this dose of radiation affect you?

Dr. GRAVES. I was nauseated for the first day. I was in the hospital for 2 weeks. I never did feel very sick but I was quite—I did not have very much ambition, I was tired, I got tired climbing steps and so on, and this lasted for perhaps 6 months. At the end of 6 months I was back to work, and I can't tell any difference now.

Representative VAN ZANDT. Did it affect your hair in any way?

Dr. GRAVES. I lost the hair on one side of my head. I did not have to shave for a while, which was a byproduct that was useful.

Representative VAN ZANDT. How about your eye?

Dr. GRAVES. I have a radiation cataract in one eye. The other eye is perfectly all right.

Representative HOLIFIELD. What was the white corpuscle count at the end of 6 months?

Dr. GRAVES. At the end of 6 months it was back to normal. You can't tell anything. You can examine me with a microscope or anything else, and you can't tell any difference now. At the time my white blood count dropped from about 8,000 or 9,000, which was normal, down to around 2,000. Again I don't have these numbers in front of me, so I don't remember exactly. But at the end of perhaps a week or 10 days the count began to increase again, and got back to normal. As a matter of fact, it got above normal. By 6 months it was back to normal, and stayed there ever since.

Representative HOLIFIELD. Dr. Graves, I think I express the feelings of every member of this committee that have known about this for so many years, that we are glad you are in as good health as you are today, and we want to again express our thanks to you for the tremendous contribution you have made to the security of our Nation.

Representative COLE. Mr. Chairman, I just want to concur in what you have said with respect to the attitude of the committee toward Dr. Graves' work. But since we have engaged in some rather personal questions of him with respect to consequences of his exposure, I would like to inquire if since that occurred you have increased your family in any way, and if so, whether the progeny is apparently normal and health. Mr. Chairman, I do not ask it facetiously. Here is a man

who has been exposed to a degree of radiation probably greater than any person that we know. He has told us the consequences to him of his own body. Since radiation exposure has been said to involve a question of sterility and so forth, unless he would rather not answer, I would like to give him the opportunity of indicating.

Dr. GRAVES. I had one daughter before the accident. I have had a daughter and son since the accident. The daughter and son as far as can be told are perfectly normal kids. We love them very much.

Representative VAN ZANDT. From a heredity standpoint, do they show any extraordinary amount of energy as a result of your brush with atomic energy?

Dr. GRAVES. Speaking as a parent they are very intelligent children.

Representative HOLIFIELD. Thank you very much. Our next witness is Dr. W. W. Kellogg of the Rand Corp. and he will speak to us on the subject of atmospheric transport, storage, and removal of particulate radioactivity.

Dr. Kellogg, how long is your presentation?

STATEMENT OF DR. W. W. KELLOGG, RAND CORP.[6]

Dr. KELLOGG. I have a report for the record which is somewhat long, and I was not planning to give it all now. It has a lot of documentation in it. I was going to abstract it to the committee orally. I could do it in 30 or 40 minutes. Is it too late to do that?

Representative HOLIFIELD. We will accept your prepared statement for the record. We will be glad to have you summarize it.

(The statement referred to follows:)

ATMOSPHERIC TRANSPORT AND CLOSE-IN FALLOUT OF RADIOACTIVE DEBRIS FROM ATOMIC EXPLOSIONS

(By Dr. William W. Kellogg, RAND Corporation)

INTRODUCTION

It is well known that the radioactive debris from an atomic explosion is carried high into the atmosphere, and that eventually all of it reaches the ground. However, there are a variety of things which can happen to these particles on their way to ground, and their paths can be quite complicated. The purpose of the present report is to describe and document part of this process of radioactive fallout.

In order to limit the discussion, fallout here will be taken to mean "close-in fallout," the fallout which occurs during the first day or two following the explosion, and which deposits radioactivity within a few hundred miles of ground

(Submitted by Witness.)

zero. The intermediate scale of fallout (that which occurs in the first few weeks) and the worldwide fallout will be treated by others.

Although the purpose is to tell what we know about fallout, an effort will also be made to point out the areas of uncertainty in our knowledge. Fallout is a process which is affected by many different things, and the atmosphere by its very nature behaves in an erratic and random way. Thus, it is fair to say at the outset that, no matter how well we could document our observations of fallout, there would still be an area of uncertainty due to the randomness of the process. This aspect should be borne in mind in considering the evidence which follows.

DESCRIPTION OF THE PROCESS OF CLOSE-IN FALLOUT

There is a fundamental difference between the fallout from an atomic device detonated at the ground and the fallout from one detonated so high that the fireball does not touch the ground. In the case of the surface burst, large quantities of surface material are broken up, melted, and even vaporized, and some of this material comes in intimate contact with the radioactive fission products. Then, after the atomic cloud has stopped rising and the violent updrafts associated with the explosion have subsided, the larger and heavier particles start falling back to the ground. The result is an area around ground zero and extending downwind which is covered in a more or less systematic way with particles contaminated by atomic debris.

In the case of an air burst in which the white-hot fireball never reaches the surface, the radioactive fission products never come into close contact with the surface material; they remain as an exceedingly fine aerosol. At first sight this might be thought to be an oversimplification, since there have been many cases in which the fireball never touched the ground, but the surface material was observed to have been sucked up into the rising atomic cloud. Actually, however, in such cases a survey of the area has shown that there has been a negligible amount of radioactive fallout on the ground. Though tons of sand and dust may have been raised by the explosion, they apparently did not become contaminated by fission products.

The explanation for this curious fact prabably lies in a detailed consideration of the way in which the surface material is sucked up into the fireball of an air burst. Within a few seconds from burst time, the circulation in the atomic fireball develops a toroidal form, with an updraft in the middle and downdraft around the outside. Most of the fission products are then confined to a doughnut-shaped region, and may be thought of as constituting a smoke ring. When the surface debris is carried into the fireball a few seconds after the detonation, it passes up along the axis of the cloud, through the middle, and can often be seen to cascade back down around the outside of the cloud. In its passage through the cloud, it has passed around the radioactive smoke ring but has never mixed with it.[1]

There has not been a large number of surface shots in the United States test series, and most of these have been set off in the Pacific area, where complete documentation of the fallout has been difficult because the greater part of the material came down in the open ocean or in the water of the lagoons. During the last Pacific test, however, a method of surveying the ocean to determine the distribution of the fallout was used which has given us some fairly complete and quantitative data on the pattern of the fallout from some larger yield devices.[2] A reanalysis of the fraction of the debris which came down within the first few hundred miles from the various Operation Redwing surface shots by Tucker,[3] based on the ocean and atoll survey made jointly by the Scripps Institute of Oceanography, the Naval Radiological Defense Laboratory, the Evans Signal Laboratory, the New York Operations Office of the AEC, the Chemical Warfare Laboratories of the Army Chemical Center, and the Air Forces Special Weapons Center, reveals that from a large yield surface burst about 85 percent falls down in roughly the first 24 hours; for a barge shot in the water of a lagoon the fraction is between 65 and 70 percent. According to Tucker, the accuracy of the estimates

[2] Van Lint, V. A. J., L. E. Killion, J. A. Chiment, and D. C. Campbell: Fallout Studies During Operation Redwing, Field Command, AFSWP, Operation Redwing Preliminary Report, ITR–1354, October 1956 (Secret, R. D.).

[3] Tucker, B. L.: Fraction of Redwing Radioactivity in Local Fallout, RAND Corp., Report in preparation, May 1957 (Secret, R. D.).

here is probably no better than 20 or 30 percent, so the good agreement which he obtained for various kinds of shots may be fortuitous.[4]

The one other piece of evidence on the fraction falling out from a surface shot comes from Operation Jangle. The Los Alamos Health and Safety Division had a number of stations downwind to record the fallout, and the Air Force surveyed a larger area by flying an instrumented aircraft at low altitudes over the desert. Two analyses have been made of the resulting fallout pattern in order to estimate the fraction of the debris which was represented, one by Lulejian[5] and the other by Rapp.[6] The results are as follows:

	Percent
Lulejian: Beyond 10 miles from ground zero and within 200 miles	60±20
Rapp: Beyond 4 miles from ground zero and within 200 miles	77
Rapp: Total fallout out to 200 miles	87

It should be noted that the famous March 1, 1954, test of the Castle series in the Pacific, which received some publicity because of the fallout on some nearby inhabited atolls,[7] was not well enough documented to enable one to get a good estimate of the percentage of fallout. In order for such an estimate to be made it is clearly necessary to be able to lay out the *complete* fallout pattern. This was not possible here, since the islands on which the fallout occurred occupied only a part of the pattern, and were probably not in the region of maximum fallout. This event will be discussed more below.

As pointed out above, if the height of burst is raised, the amount of surface material which can become intimately mixed with the fission products becomes less. As a result, the fraction which takes part in close-in fallout decreases with increasing height of burst. A tower shot does not exactly follow this trend, however, since the material in the tower itself and in the cab at the top of the tower apparently provides some radioactive fallout. The fraction falling out from a tower shot appears to be quite variable, as can be seen from the following tabulation prepared by Kenneth Nagler and Dr. Lester Machta of the United States Weather Bureau, based on a detailed analysis of the actual fallout from a number of tests in Nevada, all of which had yields in the range of 12 to 18 kt.

	Percent
300-foot tower	17.8
	12.3
	8.9
	7.8
	7.0
Average	10.8
500-foot tower	5.4
524-foot airburst (especially uncertain)	1.0

It should be noted that the particular airburst cited here produced a fireball which almost touched the ground. Higher airbursts, as mentioned above, produce no significant close-in fallout.

So far the discussion has been concerned with the *total amount* of radioactive material taking part in the fallout. The *distribution* of this material on the ground depends on a number of parameters—wind structure, yield and height of burst, and kind of surface. The yield and height of burst predominantly determine the distribution of radioactivity with size of particle, and the height and size of the cloud at time of stabilization. The kind of soil taken into the fireball presumably has an effect on the particle size distribution too. In order to make a calculation of where the debris will go, all these factors must be taken into account in one way or another. The various ways of handling this complicated situation are treated in the next section.

---

[4] In ref. 2, Appendix E, similar estimates are made which are less than the ones quoted. However, it appears that a different "normalization factor" was used to convert from kt yield to megacurries of fission product activity at one hour, and this was combined with an inappropriate decay rate to convert from the time of observation to the reference time of 1 hour. Further, Tucked introduced a correction for the radioactive sodium from the ocean water which was activated by neutrons from the explosion, and which contributed to the observed radioactivity.

Before proceeding further it might be well to mention something about what happens to these radioactive particles after they are on the ground. The largest particles involved may be a millimeter or more in diameter, but these constitute only a small fraction of the total debris. Both observation of the particles, collected in many ways in the Pacific and in Nevada, and theoretical calculations of the way in which they must fall indicated that the majority of the particles taking part in the close-in fallout have diameters between about 50 and 400 microns (1 micron is 10,000 cm.).[8 9 10 11]. According to G. R. Hilst, of the Hanford Atomic Products Operation, particles of less and about 50 microns diameter are difficult to erode by wind action because they tend to sift down and cling between the larger particles of the soil, and particles larger than about 500 microns diameter are difficult to erode because the wind cannot easily lift them. The particle size range in which radioactive fallout lies is the size which can be most easily lifted by the wind and redeposited somewhere else. Under high wind conditions this could further complicate the prediction of where the debris would go.

COMPUTING FALLOUT PATTERNS

Clearly, the direction that a particle takes on its way to the ground is determined by the wind. It is not the wind at one level alone which must be considered, but the cumulative effect of all the winds between the ground and the initial altitude of the particle. There have been a number of mehods developed to make some sort of best guess about where the debris will be deposited, and these all have one element in common: The wind field from the ground up to the atomic cloud must be analyzed and integrated.

In order to understand the matter of fallout computation, it is necessary to see what is involved in an integration of the wind field. Figure 1 shows, in schematic form, how such an integration can be done vectorially. Let it be assumed for the moment that a particle starting from 50,000 feet, for example, has a constant rate of fall. In such a case it will spend the same amount of time in each layer of a given thickness, say 5,000 feet. The direction of its travel while in a given layer will be in the direction of the mean wind in that layer, and the distance it travels while in the layer will be proportional to the length of the corresponding wind vector. Then it falls down into the next layer and again travels with the mean wind in that layer. In order to determine the total distance and direction which this particle traveled on the way to the ground it is only necessary to add the successive wind vectors for each layer head to tail, and the resultant vector will represent the total travel.

In practice, meteorologists have found it convenient to add the vectors starting from the ground and working upward, as shown in figure 1b. Now the integrated wind, or total particle travel, from any given altitude can be immediately determined by drawing a vector from the origin to the head of the arrow corresponding to the correct altitude. In other words, a family of integrated winds can be produced in this way, and the direction and rate of travel of all particles can be estimated by inspection of the diagram. Recall that it was assumed here that the particles fell at a constant rate. This is not the case in actuality, and so the simple vector addition described here must be modified in the more sophisticated analyses of fallout.

There have been four main approaches to the construction of a fallout analysis, depending on the amount of time available for the computation and the degree of completeness required. It should be emphasized that these various approaches do not compete with each other, since they are each tailored to answer a different set of questions about the fallout, and they differ greatly in the amount of labor required to carry them out. In order of increasing complexity, they are—

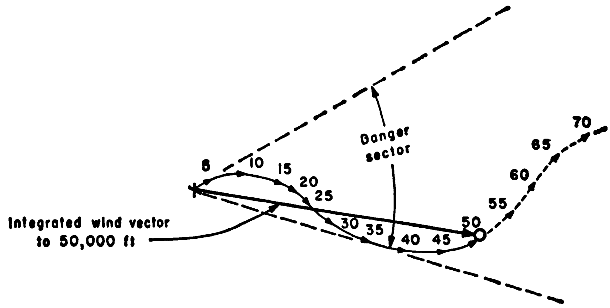
(a) Actual particle trajectory



(b) Usual method of plotting and integrating the wind field

FIGURE 1.—Schematic representation of a wind field and the analysis of a falling particle's trajectory.

1. *The danger sector.*—An inspection of the integrated wind plot shown in figure 1b shows that all the particles starting in a vertical line over the origin would travel within the sector indicated by the dashed lines. This can be called the danger sector, since it is the sector within which the debris will fall, more or less, assuming a perfectly constant wind field. Certain refinements can be made to the simple sector presentation with little effort, such as delineation of the times at which the particles starting over ground zero will reach a given point on the ground; and the finite initial size of the atomic cloud can be taken into account graphically. This approach has been described in detail in several readily available reports.[12 13 14] Since it is quick and convenient, it is the method which has been recommended by the Weather Bureau, the Air Weather Service, and the FCDA for use in weather stations in an emergency. In order to further expedite the computation, the Weather Bureau has recently instituted the inclusion of the integrated winds from each upper wind station in the routine teletype message. These go by the code name of "UF winds," and are available from about 70 weather stations within the United States twice daily. Note, however, that the danger sector method does not provide a way for telling the actual levels of activity and does not distinguish the parts of the sector which are more intensely contaminated, though there are some methods for roughly estimating where these will be.

2. *The idealized pattern.*—Several of the earlier workers in the field of fallout noted the fact that the majority of the patterns (in Nevada) had a characteristic cigar shape.[5 15] It was therefore tempting to attempt to characterize fallout patterns in general in terms of a family of simple elliptical shapes, with a circular

section around ground zero. The Armed Forces special weapons project (AFSWP) and others have, over a period of years, developed rather elaborate sets of scaling and shaping laws, designed to fit these idealized patterns to a wide range of yields and, to a limited extent, wind conditions. These methods are described in detail elsewhere.[16] A recent report of the Air Force Special Weapons Center by Boyd and Baker has summarized and made comparisons of the various methods.[17] They all have the common characteristic that the only input required is the weapon yield (a surface burst is assumed) and some sort of an integrated wind, sometimes called the effective wind. For certain planning purposes these idealized fallout patterns are quite useful, since they give a good idea of the area covered by a given dose contour, and for a simple wind structure the orientation and shape may be quite representative. However, as our experience with actual fallout patterns grows, it becomes clear that the simple wind structure required to lay down a symmetrical pattern like the idealized ones is not necessarily the expected one, particularly in the Tropics or in Nevada in summer. Therefore, for prediction purposes such a method may be of little value; moreover, the way in which it is presented gives an erroneous impression of the accuracy of the plot, since the dose rate contours are actually specified.

3. *Analog method.*—A very common technique in weather forecasting, one which all meteorologists use either subconsciously or consciously, is the use of analogs. Essentially, this means a sorting over of cases which have occurred in the past to find a situation analogous to the current situation, and presuming that the same processes will follow the same course again. There have not been enough surface bursts to build up a good file of analogs, but an artificial set can be calculated, using the sort of detailed calculations to be described in the next section. Such a "catalog" of fallout patterns has already been produced by the Rand Corp.[18] To make use of this collection of analogs, the meteorologist must find a wind field in the catalog which by proper manipulation can be more or less matched to the current wind field, and he can then take advantage of the fact that the resulting fallout pattern has already been computed in great detail. If the yield does not match, then certain scaling laws can be applied to the analog to make it the correct size. Naturally, the same wind field never occurs exactly the same way twice, but the matching can be done quite successfully over a wide range of conditions and yields.

4. *Fallout models.*—In attempts to describe as closely as possible what actually happens in the fallout process, several agencies have developed techniques in which the particles in the initial atomic cloud are traced down to the ground, and in which their combined effect is then calculated for each point in the fallout field. The result is a polt of the expected dose rate at any given point for a given time. In order to perform such an elaborate computation the following factors must all be considered:

Wind field—in some of the computations it is not only possible to consider the variation with height, but the variation with time and space. Under certain conditions, as will be shown, such variations are quite important.

Initial distribution of particles in space—although the size and shape of the atomic cloud can be observed photographically, the distribution of the radioactivity inside the cloud is not well known. Assumptions about this vary from model to model.

Size distribution of the particles—since the larger particles will in general fall faster than the smaller ones, it is necessary to specify how much of the total radioactivity is associated with each range of particle size. Furthermore, the size distribution probably differs in different parts of the cloud, a feature which some of the models attempt to take into account.

Rate of fall—the rate of fall of a particle depends on its size, density, and shape. Thus, the rates of fall of a given size particle at each altitude must be specified in each model.

Turbulent diffusion—in at least one of the models which has been tried the spread of the trajectories due to random turbulence has been taken into

account. However, most of the models choose to neglect this effect, since it does not appear to be very important for the early deposition.

Each of the computational models must specify all of the above factors, and there have been some rather large differences between the assumptions, due to our lack of very definite information about the true facts of the matter. In addition, different computational techniques are used to analze the model, some using high speed digital computers, some using special electronic or optical analog computers, and some using a graphical "hand" computation.

In January 1955, the Armed Forces Special Weapons Project (AFSWP) organized a symposium on radioactive fallout, and all the various agencies which had studies the question of fallout were invited to apply their respective fallout models to two specified sets of wind conditions, known as condition A and condition B. The results, as published in the AFSWP report on the symposium [19] are shown in figures 2 and 3. The winds used are tabulated in table 1 and table 2. For details of the actual computational schemes used, one should refer to the fallout symposium report [19] or to the reports of the various agencies, some of which have become unclassified.

Height (feet, mean sea level)	Wind direction (degrees)	Wind speed (knots)	Height (feet, mean sea level)	Wind direction (degrees)	Wind speed (knots)
Surface	Calm	0	45,000	292	23
5,000	358	11	50,000	290	28
10,000	009	20	55,000	290	20
15,000	325	14	60,000	268	11
20,000	282	19	65,000	276	21
25,000	263	34	70,000	293	7
30,000	263	47	75,000	293	8
35,000	273	37	80,000	285	10
40,000	308	27	85,000	250	11

The significant thing to note is the discouragingly poor agreement between the various results. It is possible that some of the agencies have modified their models in the past 2 years, and that there would be better agreement if the exercise were repeated now, but it is highly unlikely that the agreement would be anywhere nearly exact. It would seem that we simply do not know enough yet about the process of fallout to be able to reconstruct a fallout model (no matter how sophisticated in conception) on which everyone would agree.

PREDICTION AND RECONSTRUCTION OF FALLOUT PATTERNS

As stated in the previous section, there have been a number of methods develeped for the computation of fallout patterns. Naturally, these were developed with the observed fallout from a handful of surface and tower bursts in hand, and all claim (to a greater or lesser degree) to give results which agree with reality.

The real question of agreement with reality is, however, obscured by the fact that reality is hard to define, even in retrospect, when all the facts are collected. First, the wind field is poorly observed, and the variations in the wind field with time and space are difficult to take into account in reconstructing what

happened. The meteorological literature has a number of studies of this variability and of the uncertainties in observation.[20 21 22] A good rule of thumb, derived from experience with the tracking of constant-level balloons, is that, over a good upper air network of the sort which covers the United States, the path of a particle cannot be determined from an analysis of the wind field to better than 20 percent of the length of the trajectory. Thus, after going 100 miles, the uncertainty in the position of a drifting particle is about 20 miles, even when we have all the upper-air data which we can lay our hands on.

Furthermore, the fallout itself is poorly observed, due to the great distances that have to be covered, the irregularities of the terrain (in Nevada) or the uncertainty of where it went after landing in the ocean (in the Pacific). Thus, even if our computation were, in principle, a perfect one, we would still not have a clear picture against which to compare it.

When the meteorologist is faced with the problem of *predicting* a fallout pattern, the uncertainties of a wind prediction are added to the uncertainties in the computational model. The longer the time lag between prediction and the event, the greater will be the uncertainties.[23] For times of up to 12 hours, it appears that persistence is about as good as a forecast, and after about 2 to 3 days a forecast is not much better than a climatological mean.

Without belaboring this point, it should suffice to show two interesting examples of predicted and reconstructed fallout patterns. One is from a burst of roughly 30 kilotons on a tower in Nevada, the Open or Civil Defense shot of May 5, 1955. The patterns shown in figures 4 and 5 were prepared by Kenneth Nagler, of the United States Weather Bureau, and show the patterns which were predicted 2 hours before shot time by 2 methods of models. The two models, one of the Weather Bureau and the other of the Los Alamos Scientific Laboratory and the University of California Radiation Laboratory, were used. The first involved a hand computation by an elaborate graphical analysis, the other involved a high speed digital computer (IBM–701). There were some differences in the two models, but these were not basic ones—that is, they both used the general approach described in the previous section. It will be noted that both methods predicted patterns extending due north from the shot point, following the direction of the H–2 hour predicted wind. The observed pattern, shown in figure 6, was reconstructed from the available road monitoring and from a few aircraft measurements by Nagler. The fallout started out northward, and then curved to the eastward, reflecting a gradual shift in the wind direction from south to west that took place in the hours following the shot. Also shown in figure 6 is an attempt to reconstruct the pattern, using the Weather Bureau's model and taking into account the change of wind with time and space. The result agrees with the obesrved pattern better, but still not perfectly.

Another example of a fallout pattern which changed its direction during the later stages of the fallout is the March 1, 1954, Castle shot on the Bikini atoll, referred to earlier. In this case, the fallout apparently started out in a direction east-northeast, but a continued veering of the wind caused it to curve more to the east and east-southeast, until one side of it lay across some neighboring atolls. A study of this event by Rand in which the fallout was computed with the shot-time wind alone, and then again with the variable (true) wind, shows clearly how the pattern must have curved as it progressed.[24]

It is interesting to note that both of these examples demonstrate the effect of the changing wind with time, an effect which is often very hard for the meterologist to specify. A study of the statistics of this change of wind with time has been made by Frank Cuff, department of meteorology, University of Utah.[25] Referring to the integrated wind (see above) from the ground up to various altitudes in Nevada, he found the mean absolute bearing changes shown in table 3.

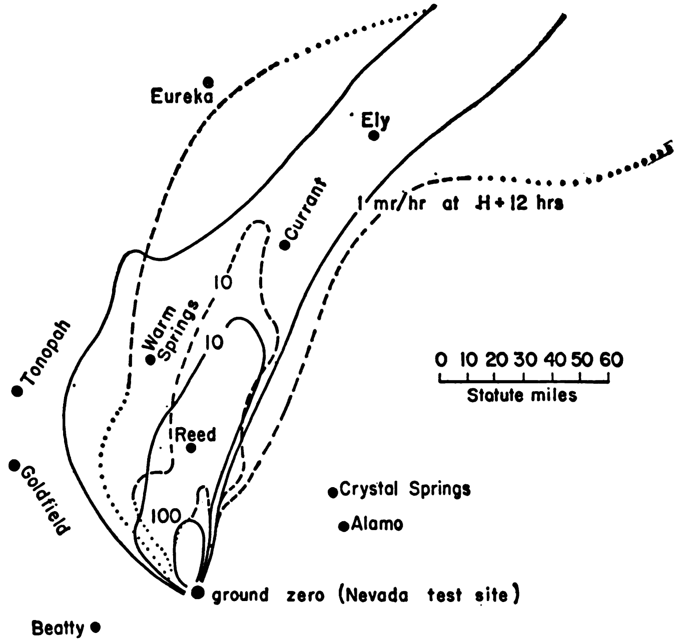

FIGURE 6.—The observed fallout distribution (dashed lines) and the pattern reconstructed by the Weather Bureau using a hand computation with time and space variation of winds (solid lines). May 5, 1955.

TABLE 3.—*Mean absolute bearing change of integrated winds*

Time interval (hours)	Integrated wind from surface to—		
	20,000 feet	40,000 feet	50,000 feet
3	12°	7°	6°
6	22°	15°	13°
12	33°	28°	

It will be noted that the bigger the thickness of the atmosphere considered in forming the integrated wind the smaller is the shift of the wind. This probably reflects the fact that wind shifts at one level may sometimes be partially canceled by opposite wind changes at another altitude. Another lesson to be learned from this study is that the statistics of the wind at one level cannot be relied upon to give reliable information about the statistics of the integrated wind, which must combine the effects at many levels.

A recent study of the predictability of fallout for the Nevada test site has been made by Jack Reed of the Sandia Corp.[26] Here the variability of the wind, the forecasting accuracy, the length of the forecast period, etc., are all considered in order to given an estimate of the degree of confidence with which the fallout can be put into an uninhabited "safe sector." This approach to the problem is one which should be taken more often in meteorology, since it demonstrates that any weather forecast should have a prabability assigned to it—a probability which is always less than one.

THE DYNAMICS OF FALLOUT

So far a great deal has been said about the final fallout pattern and how it is computed. A very important feature of the pattern from a practical standpoint

[26] Reed, J. W.: Estimating Safety Probabilities From Fallout Forecasts for Nevada Test Site, Sandi Corp. report SC–4073 (TR), February 1957.

is the *time* at which the fallout reaches various parts of the pattern. Clearly, the fallout cannot all occur at once, since it takes some time for the particles to reach the ground, and while they are falling they are carried with the wind. Thus, the fallout around ground zero starts very quickly, whereas the fallout miles away may not start for hours. (For example, the island of Rongelap did not receive its fallout until some 4 to 6 hours after shot time.[7])

Recall that, for a surface burst of more than a few kilotons yield, most of the radioactive debris is in the mushroom cloud. When the yield is several megatons, this mushroom cloud rises into the stratosphere,[1] and so even the relatively infrequent larger particles, of 1,000 microns diameter and over, take from 30 to 40 minutes to fall back to the ground. It appears that there are some few radioactive particles which escape from the mushroom while it is rising and are left behind in the stem cloud, and these will, of course, find their way to the ground sooner, in the downwind direction.

In order to demonstrate the time of arrival of radioactivity at points relatively close to ground zero, the Naval Radiological Defense Laboratory[9,10] and the Army Chemical Corps[11] have designed equipment which records the fallout as a function of time. Though their respective instruments were designed independently, they both work on essentially the same principle: A small tray or container is uncovered for a certain period of time (say, 5 minutes), then covered again. Automatically the next sampler is uncovered for its sampling period, and so on. It should be mentioned that both sets of instruments remained closed for the first minute after shot time, to allow the shock wave to pass the sampling station.

A large number of such fallout versus time measurements were made at the time of the Castle shot 1, and a few had been made earlier at the Ivy Mike test by NRDL. When all the results using 5-minute sampling times (20 cases) are plotted up one is impressed, first of all, at the erratic nature of the results. This is probably due to the fact that the samples are made with small areas and small time intervals, and therefore do not give results which are entirely representative of the fallout at that location.[37]

The next thing which one notices about the results is that the majority of them show *no fallout for the first 30 minutes;* the average time of arrival for all stations which received any fallout was 28 minutes. These stations were located at distances from ground zero ranging from 8 to 30 miles. In visualizing these distances, recall that the Ivy Mike cloud had a radius of about 5 minutes of 10 miles, and at 10 minutes it was nearly twice this. For the Castle shot 1 the radius at 10 minutes was about 30 miles, and still growing. Thus, all the stations represented were literally in the shadow of the great mushroom cloud—though none were in the initial part of the stem.

The few stations which did apparently receive fallout earlier may have had something wrong with their mechanism (as would appear to be the case where two nearby stations give completely opposite results), or they were in a direction from ground zero which allowed them to be dusted by the material from the crater area which was born by the low level winds. This latter explanation appears to be reasonable, since we know that a certain small fraction of the radioactivity produced does reside in the stem cloud at relatively low altitudes.

It is therefore tempting to visualize the fallout as a slowly descending blanket, with a diameter roughly the diameter of the mushroom cloud. The blanket starts its fall as soon as the atomic cloud stabilizes (about 4 to 6 minutes after burst time) and touches the ground over a large area simultaneously. While this mushroom material undoubtedly represents the major fallout, some material from the stem may reach the ground sooner, and the direction of this immediate fallout from the stem would be determined by the mean wind in the lower levels, below, say, 20,000 feet.

Following this early arrival of the radioactive debris the fallout pattern is laid out in a more or less orderly way and spreads in the direction of the integrated winds. To illustrate how the pattern grows with time, figures 7 and 8 show the growth of a hypothetical 1 megaton pattern under 2 very different wind conditions. One shows how it grows under a condition where the winds are moderately strong and all in the same general direction. The other shows how one grows under a low wind condition. In the first case the debris is spread rapidly in a ribbon across the country. In the second case the debris continues to fall in the vicinity of ground zero for many hours. Neither of these wind conditions is particularly unusual, and there are naturally an infinte number of possible intermediate cases.

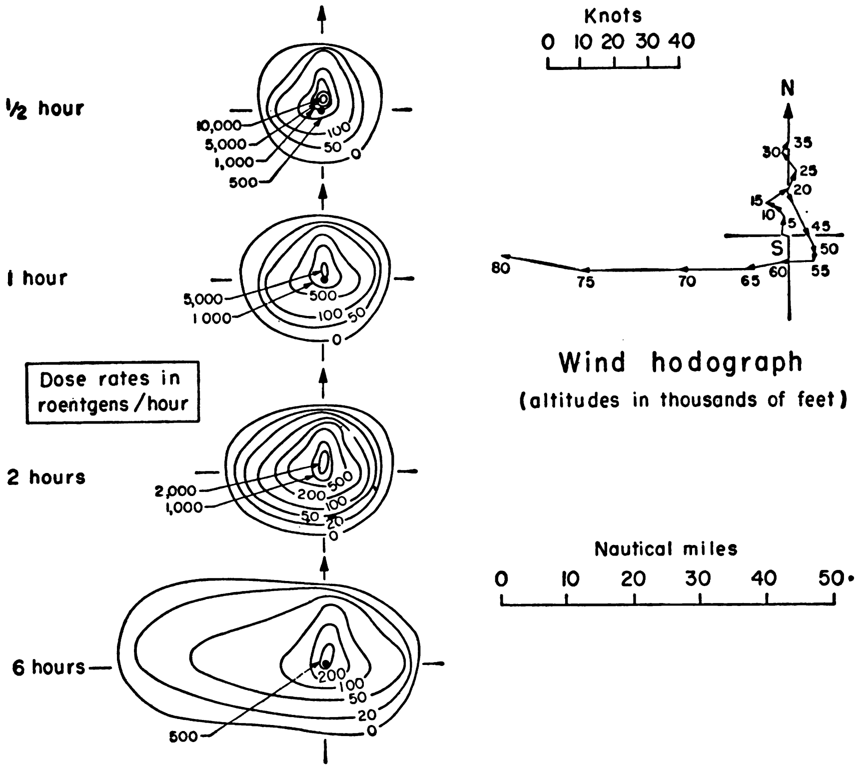

FIGURE 8.—Calculated fallout from a 1 MT surface burst with a two-thirds fission yield under a "low wind" condition. Winds are those for Atlanta on June 15, 1954.

FALLOUT FROM A BOMBING CAMPAIGN

No discussion of fallout would be complete without some discussion of the results of a bombing campaign, in which many bombs are set off against a target system with a large number of widely dispersed aiming points. Such a target system might be, for example, the industrial complex of the United States, or its system of airbases, providing targets which are located in a more or less random manner over the entire country.

The natural laws governing the fallout from such a campaign are the same as those governing the fallout from one burst. The difference lies in the fact that now the fallout patterns overlap in places and reinforce each other. Furthermore, where the ground zeros are fairly close to each other the fallout is more or less independent of the wind direction, since it makes little or no difference which bomb causes fallout on a given spot—such an area is "blanketed."

A number of studies have been made of such campaigns,[28 29] and a technique has been developed by Greenfield for estimating on a probabalistic basis the results of fallout from multiple-bombs dropped randomly in a large area.[30] One such study, in which the hypothetical fallout was computed for an attack on the United States under a rather typical meteorological situation, was performed by Charles K. Shafer, headquarters, Federal Civil Defense Administration, Battle Creek. It was done in connection with the FCDA's Operation Sentinel.

[28] Davidson, H. D., J. B. Green, J. B. Phelps, C. D. Stolzenbach: Fallout as a Threat from Attack by Manned Bombers, Operations Research Office, Johns Hopkins University, ORO–R–17, appendix C, September 1956 (secret).

[29] Rapp, R. R.: Fallout Computations for Operational Studies, Rand Corp., RM–1753, July 1956 (secret, R. D.).

[30] Greenfield, S. M.: Radioactive Contamination from a Multibomb Campaign, Rand Corp., RM–1607, January 1956 (secret, R. D.).

Though this represents just one particular combination of events, it is instructive to see what would have happened under this hypothetical attack, according to Shafer.

In this exercise about 250 nuclear (or thermonuclear) weapons with "damage zones" ranging from 3 to 5 miles were dropped on cities, industrial targets, and airfields through the United States. The combined fallout pattern from all these bombs is shown in figure 9. The details are contained in an unpublished report by the FCDA, and the following are some of the general conclusions which were drawn with regard to the effect of such an attack on the United States population:

	Dead	Injured	Uninjured
1st day	36,000,000	57,000,000	58,000,000
7th day	51,000,000	42,000,000	58,000,000
14th day	61,000,000	31,000,000	58,000,000
60th day	72,000,000	21,000,000	58,000,000

These numbers are based on 1950 population figures. Those dead on the first day were presumably killed by the immediate effects of the bombs, i. e., mostly blast and thermal effects. The subsequent rise in fatalities reflects the delayed effects of radiation damage, coupled in many cases to external injuries. While one should not take these actual numbers too literally, their orders of magnitude and the trends shown here are fairly realistic. In particular, the indication that fallout might account for a large number of deaths—nearly as many died by the immediate effects—is pertinent. In actuality, many of the "uninjured" ones would be caught by the fallout as they tried to move about. Clearly, however, such figures can only be illustrative, since the behavior patterns of the population would have a tremendous effect on the casualties due to radiation. While the meterorologist can predict to some extent the fallout patterns, he can hardly be expected to predict whether or not the population will be trained and provided with adequate shelters before such an attack.

Dr. KELLOGG. I am with the Rand Corp. at Santa Monica, Calif., at the present time. I am head of what we call the geophysics group. The geophysics group is composed to a large extent of meteorologists and atmospheric physicists, and we have been interested in studying the subject of radioactive fallout for a number of years.

I feel somewhat inadequate for the job of presenting all the material which I want to present today, partly because it is a complicated question, and partly because I feel that there is still some difference of opinion among meterologists on the details of this question of close-in fallout. I hope that I can not only reflect sort of a consensus of opinion, and my own opinion, but also indicate where we feel that we need to have more information on the subject of close-in fallout.

Before I start, I would like to make three rather general statements which in a sense are threads of the whole thing which I am presenting.

The first is one which I think you have already sensed from the testimony of Dr. Graves, to the effect that radioactive fallout is a major effect from an atomic explosion. I therefore feel that we should make all the pertinent facts available to the public and to the military on this question because one can't consider an atomic explosion and its effects without considering radioactive fallout.

The second point I would like to make very briefly is this.

Chairman DURHAM. May I ask a question at that point? Has your company been doing this all the time—making the information available to the public and also to the military?

Dr. KELLOGG. We have tried to very hard. In the January issue of the Journal of Meterology, for example, the work on close-in fallout

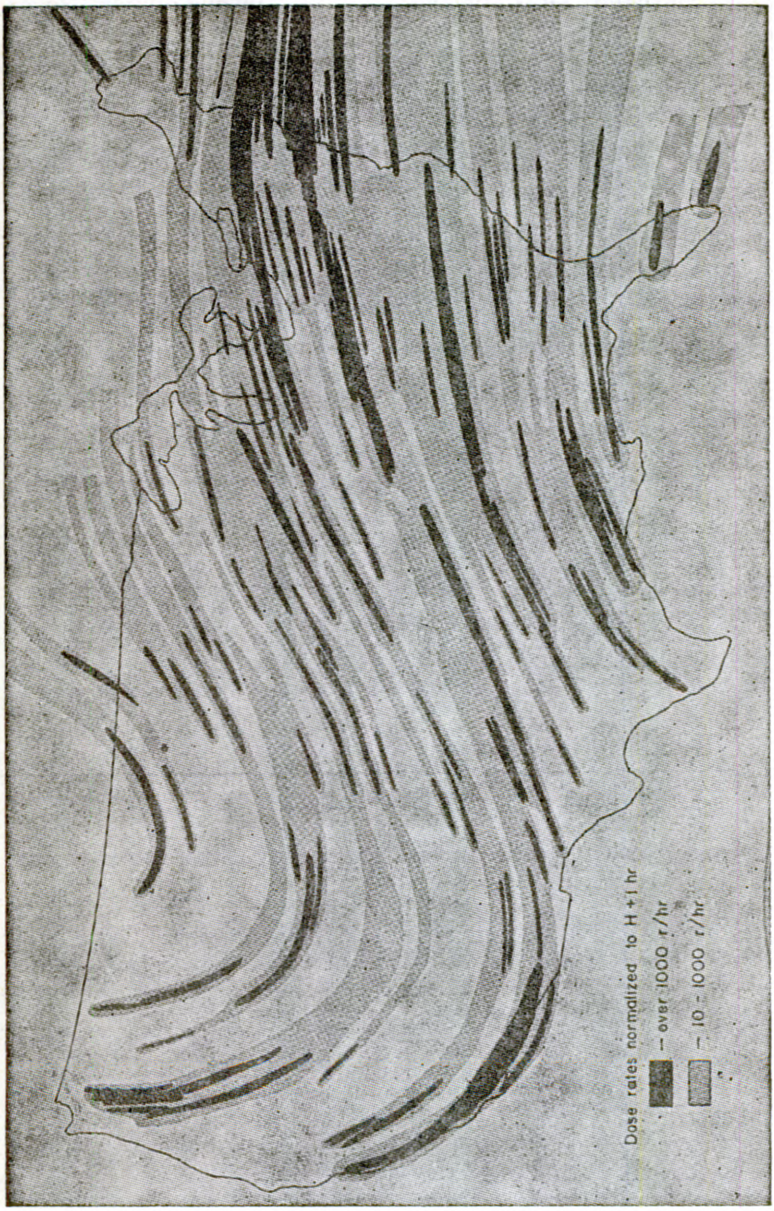

FIGURE 9.—Fallout condition computed by the FCDA for Operation Sentinel.

which our group has done was summarized. It is an article which appeared in what you might call the official United States meteorological journal by Dr. Rapp and Mr. Greenfield and myself. There have been other outputs from our group that have to do with other facets of fallout which we have published as fast as we could get them into the open. We have made an effort in this direction.

The second point I was going to make has to do with feeling that I think every meteorologist would share with me, that we are often charged with an impossible job of predicting exactly how the atmosphere will behave over a long period of time in the future. I think one of the points to be made is that there is always an element of uncertainty in a meteorological forecast. This should be kept in mind when we speak of the prediction of fallout patterns.

The third point that I think should be made in connection with close-in fallout is that when we speak of close-in fallout, as Dr. Graves pointed out, we must try to figure out how much of this material does come down in close-in fallout, because this determines what is left over to go worldwide. So I will spend a little bit of time defining what we know about the fraction which falls out close in, because this will have bearing on the worldwide problem, too.

Representative HOLIFIELD. Your company has made a study of this under a contract with the AEC or with the Defense Department?

Dr. KELLOGG. In 1953, our company accepted a contract with the AEC to study various aspects of fallout. This ran for 3 years. I believe it was 3 or 3½ years. We no longer operate under this contract. Our work is now primarily for the Air Force. Under our prime contract with the Air Force, we are continuing our work on this matter.

Representative HOLIFIELD. Your reports have been made to the Atomic Energy Commission for the 3 years, and you are now making reports to the Air Force; is that right?

Dr. KELLOGG. That is correct; yes. Most of our work is now for the Air Force, but we maintain close liaison with the AEC in our work.

Representative HOLIFIELD. Are you under any directions in regard to security in testifying before us today on this matter?

Dr. KELLOGG. No. I am happy to say that although I wrote the testimony which is here, and submitted it to both AEC and the Department of Defense, it has been cleared. Essentially everything I wanted to say they have allowed me to say.

Representative HOLIFIELD. Does your testimony bring up to date your findings?

Dr. KELLOGG. Yes.

Representative HOLIFIELD. You may proceed.

Dr. KELOGG. Dr. Graves pointed out that there is a big difference between an air burst and a surface burst and the fraction that falls out. Since he has covered this so ably, I will not go over this in detail. You understand about this business of the surface material being mixed in the fireball when the detonation is on the surface.

In the case of a tower shot, which is sort of an in-between case, the fraction which comes down is variable, in the complete report, in order to demonstrate how variable this is, I have taken some numbers which were given to me by Mr. Nagler, of the Weather Bureau, who has made a very careful analysis of the fraction which fell out from

five detonations, all of about the same yield. All had about 15 kilotons yield, and all were on the same height of tower.

The interesting thing was that they varied over a rather wide range in the fraction which came down. This, I think, is probably due to the fact that the meterological conditions and the way in which the tower was made, the amount of material around the test device, and so forth, all varied.

Representative HOLIFIELD. Do you mean by that that the fallout was uneven and in some places there was a heavier dose than others?

Dr. KELLOGG. This is true, of course. It is not just laid down uniformly. The thing which I was speaking of at the moment was the total fraction which comes down in the first 24 hours in the part of the country which is carefully monitored so we can keep track of it, in other words.

Representative HOLIFIELD. There was a great variation in the reading of your instruments?

Dr. KELLOGG. When all the information from all the instruments was in and analyzed, and the Weather Bureau or the Health and Safety Division was able to analyze this, they were able, as it were, to count up all the radioactivity over the entire area, and get a total budget. They knew how much went into the atmosphere. They were able to see how much came down. They could say that this was some fraction of the amount produced.

Representative HOLIFIELD. But that was in the nature of a fraction of the total fallout, and it was not a measurement of the degree of the dose in that area, or was it both?

Dr. KELLOGG. It was both. In order to determine the fraction which fell out, the thing which is measured is the dose.

Representative HOLIFIELD. What was your variance between the high dose and the low dose?

Dr. KELLOGG. Later on I can show you a chart—I am glad I came prepared with a chart—showing an example of just how it does vary in the test area.

Representative VAN ZANDT. Doctor, we have been talking about the fallout coming down and going up. For a kiloton yield, how many pounds of radioactive debris does it lift into the stratosphere?

Dr. KELLOGG. I don't know the number. You mean for a surface burst.

Representative VAN ZANDT. Yes; for a surface burst.

Dr. KELLOGG. I don't know exactly. I think Dr. Graves mentioned something about a ton per kiloton or something like that.

Representative VAN ZANDT. Dr. Graves said the figure he used would be debatable. The reason I ask the question is that Dr. Libby some months ago made a statement in which he said that for every 20,000 tons of TNT yield 2 pounds of radioactive fallout is lifted into the heavens. Then he went on to explain that within a matter of weeks most of it will have fallen out. Then he talked about the megaton yield, and how it was lifted into the stratosphere, and that it may remain there from a few seconds to 10 years. Would you concur in such a statement?

Dr. KELLOGG. These numbers, I think, are a little confusing, about the 2½ pounds per kiloton. I don't know what he was referring to Perhaps he meant radioactive debris.

Representative VAN ZANDT. That is correct.

Dr. KELLOGG. The important thing seems to be that the fraction of the total debris which is produced does not depend on the yield as much as it depends on the height of the burst. What I mean to say is this. We have a case in Nevada of a surface shot for which we could measure the dose around the countryside and make an estimate of the fraction of that low-yield device in Nevada which came down. The various estimates are produced here. It looked as though something like 80 or 85 percent of the material from that low-yield surface burst came down somewhere in the first 24 hours. Then in the Pacific, although it has been very hard until recently to estimate what this fraction was, during the last test a system for monitoring the oceans has been developed and by an analysis of this ocean monitoring again we are able to make a rough estimate of the fraction which comes down in 24 hours.

Again, although the estimates vary, a good estimate seems to be around 80 or 85 percent for surface bursts. This is over a very wide range of yields.

Representative COLE. When you speak of a surface burst, do you include a tower test?

Dr. KELLOGG. No; I do not. A tower seems to produce less fallout fractionwise. An air burst produces virtually no close-in fallout. Mind you, my subject is close-in fallout, so I will stick to this amount that comes down in the first 24 hours.

Representative HOLIFIELD. You may proceed.

Dr. KELLOGG. The meteorologists who are concerned with a study of fallout are naturally interested in how to keep track of the debris. I don't propose to give a lesson on how to compute fallout patterns. I think, though, that it would be constructive for the committee to know that these are four main schools of thought on how to predict or reconstruct fallout patterns.

The four main schools of thought—and I will show a chart in just a moment—all require one input, and that is the wind information. In order to tell the direction the fallout goes, the wind must be observed, and if it is a prediction, the wind must be predicted. This is an essential ingredient to any fallout calculation, obviously. In actually doing this, the wind all the way up from the ground to the height of the atomic Cloud has to be taken into account, since the particles start up high when the cloud stabilizes, and start to fall, and they spend a certain length of time in each layer as they wall. So the distance which they travel on their way to the ground will, of course, be the cumulative effect. We refer to this cumulative effect in terms of the integrated wind, as we measure it.

This integrated wind, or cumulative wind, up to some altitude is so essential to a fallout calculation that the Weather Bureau, at the request of the FCDA, has recently gone to a system of teletype messages twice a day from about 70 stations in which a kind of integrated wind appears in the regular wind transmission. This is to make the integrated wind immediately available in any Weather Bureau station in the country.

Representative COLE. Would you explain what you mean by integrated wind? I do not understand.

Dr. KELLOGG. Yes. I If I can take just a moment, I can draw a picture. Dr. Graves mentioned that we have all been teachers at one time or another, and we reach for a blackboard whenever we can.

The use of the word "integrated" is perhaps a little too fancy. It really means we are just adding winds together to get some sort of resultant wind.

If we can represent the wind at any one level by a vector, a particle traveling through this layer will travel in the direction of the vector, and it will go a distance proportional to the length of the vector. If it travels through this layer and falls down into the next layer, it will find itself then traveling with the wind at that layer. So it will start curving and follow that new path. Perhaps the wind at the next layer down will be different again. After we have added the winds at a number of layers together, we might have a curving path something like that, representing the horizontal projection of the particle's trajectory. We have added vectors, and we have gotten the resultant as the particles travel through a number of layers and finally reach the ground. This is what we would call the integrated wind, or the effective wind, the path which the particle finally took.

Representative COLE. Does that mean the mean of the wind influences?

Dr. KELLOGG. This is the total effect of the wind on the particle as it fell from the place it started to the ground. You might think of it as the "mean." I think that it would be fair to call it the mean effect.

This is an essential ingredient to any fallout calculation. I have a chart here which will show the four main schools of thought for computing fallout that I mentioned. Very briefly I will go over these various schools of thought.

Here I have sketched in a little vector addition such as I have on the board. This is the kind of thing which is very easy to compute. In general, no matter where the particles came from in the atmosphere, one of the integrated winds will be a line connecting the origin of the vector plot with the end of one of these vectors. Just by inspection of this little diagram you can see that no matter where the particle started from, it has got to be in this sector between the dashed lines. So this is just the simplest kind of fallout calculation. It merely says there is a "danger sector," and somewhere in there there will be fallout.

Chairman DURHAM. You are talking to what height?

Dr. KELLOGG. Our usual radiosonde wind flights go to 60 to 80 thousand feet, and with a big effort they can be made to go higher. This is usually high enough to establish where the danger sector will be. If very large yields were to be involved one might be interested in winds still higher than our usual radiosondes can go.

The next school of thought, if I can refer to it as that, is known as the "idealized pattern." I have not seen the new book which AFSWP has prepared, which you have in your hand. AFSWP has been one of the chief exponents of the idealized pattern. Essentially it started with the observation in the early days of fallout that fallout patterns often look sort of cigar-shaped, and it was tempting to try to characterize all fallout patterns as a simple elliptical shape with a circle around ground zero. Then various rules were established for shaping them, making them fatter or skinnier or longer or shorter, depending on the yield or the wind.

The idealized pattern is a very useful method where one wants to characterize fallout for planning purposes. But it has not found much

acceptance where one is interested in a prediction, because the predicted patterns are apt to be more unideal.

Representative COLE. Ideal from what standpoint?

Dr. KELLOGG. They can be characterized by a simple ellipse like this.

Representative COLE. I still don't understand what is intended to be the ideal.

Dr. KELLOGG. Idealized in the mathematical sense, I guess, in that you can characterize it in a sort of perfect shape.

Another method for predicting fallout patterns and one which appeals to meteorologists—because every meteorologist when he makes a forecast of weather looks at the present weather pattern and searches his mind (or his files if he is well organized) to try to find something like it in the past, and then he will say to himself: "What happened in the past will probably happen again, so I will use this back pattern or analog as a prediction tool. I will simply see what happened the day following that previous case which was like the case today."

An analog method could be used for predicting fallout if we had a big collection of fallout patterns, and the winds that went with them, and then we would just match winds and scales taking into account the yield and we would be able to have a fallout prediction. However, we have not had very many actual fallout patterns to look at. So we really have not been able to build up a real file of analogs. The only file of analogs that we can draw on is one which is computed theoretically. As a matter of fact, the Rand Corp. has published, unclassified, something which we call "the catalog of fallout patterns," on the basis of which one can begin to use an analog method for prediction.

The most complete characterization of fallout is usually started with what is known as a "fallout model." A few agencies have taken the bull by the horns and have set up very complicated computing schemes for tracing each particle down to the ground from each level, each particle size, and adding up the effects on the ground. Of course, no one computing scheme could actually trace each particle, but there are shortcuts, and various agencies have developed practical computing schemes based on some kind of a fallout model, which reproduces the fallout as accurately as it can be done by theoretical methods.

Representative HOLIFIELD. Let me ask you this question. There are a number of these patterns in the AFSWP book.

Dr. KELLOGG. Idealized patterns.

Representative HOLIFIELD. There is an idealized pattern here. There are different kinds of patterns in here. I notice that in 1954 high yield explosion at Bikini that it gives a long pear shaped pattern. It starts out with a 5,000 roentgen yield and it goes at the end of 60 miles to 3,000, and at a little over 100 miles it is 2,000 roentgens, at 130 miles it is 1,000 and at 160 miles it is 500. That is at 36 hours.

Dr. KELLOGG. Mr. Chairman, these are probably cumulative doses, aren't they?

Representative HOLIFIELD. Yes, over the 36 hours. I was going to ask you about that. Dr. Graves spoke today about receiving 200 roentgens. As I remember the description of that accident, it was just for a moment. The question I want to ask you is this: Would 200 roentgens received in an instant be equivalent to 200 roentgens received over a longer period?

Dr. KELLOGG. This is a biological question. I prefer not to answer this in any detail. My biologist friends tell me that there is a certain amount of leeway there in the time in which one could accept it. If you get it within a relatively short time like a few hours, it is equivalent to getting it all at once. This is something which I think the biologists should comment on.

Representative HOLIFIELD. Very well.

Dr. KELLOGG. In order to give you a feel of what actually happens under fallout conditions, I have three charts which I can go through very quickly. They were prepared following the open or civil defense shot on May 5. This is a chart which was prepared by Mr. Nagler, who has made a detailed study of the fallout from a number of the tests in Nevada.

This first chart (p. 114) shows the fallout from the May 5, 1955, civil defense or open shot, which was roughly 30 kilotons on a tower. This is a map showing a few of the landmarks, Goldfield, Tonopah, Warm Springs, and so forth. You notice the scale of miles here, 60 miles as the total scale. In red is the observed fallout as deduced from an extensive system of road monitoring and from a few aircraft observations in that area. You see it goes out several hundred miles.

This little red line here is 100 milliroentgens per hour at 12 hours. The next red line is 10 milliroentgens per hour at 12 hours, and the outside one is 1 milliroentgen per hour at 12 hours. These blue lines here were a noble attempt to reconstruct the fallout taking into account all the wind observations at the time, and a careful synoptic analysis of the fallout. Here you can see the blue and red lines following fairly close to each other, the 10 and 10 and the 100 and 100. You can see the close-in fallout was reproduced quite well. In fact, the general curvature of the pattern toward the east was reproduced very well. It is important to note the curvature toward the east, because this is the kind of thing I was talking about when I said that a meterological forecast is a tough thing.

Representative COLE. Before you take the chart down, does the blue line indicate the forecast of the weather people with respect to the wind?

Dr. KELLOGG. No. This is a reconstruction. The next chart (p. 113) shows a forecast.

Representative VAN ZANDT. Did this fallout move as a mass and did it continue to move as a mass, or did it break up eventually?

Dr. KELLOGG. In this case it continued to move as a mass. In other words, it started falling here close to ground zero first, and then it was laid down in a fan shape curving to the east. It occurred earlier close in and later and later as you go along in the pattern. Heavy particles were landing close in, and lighter particles which drift longer landed further out.

This next chart (p. 113) is a prediction. This is the Weather Bureau's prediction, using the winds predicted at 2 hours before shot time. I think this is the kind of thing that one would expect. Very good verification in close. After all, this is where it is important. But then it was pretty hard apparently, in this case to predict the later shift, which must have occurred as much as 12 hours later.

Representative COLE. Is your scale the same in this chart?

Dr. KELLOGG. Yes. The scale is exactly the same. It is the same map. The red lines are exactly tracing the red lines you saw before.

Just to show the Weather Bureau is not the only outfit making predictions, this was the Los Alamos Scientific Laboratory and the University of California Radiation Laboratory prediction. They also have a forecast team of meterologists. Here again the prediction made at 2 hours before the shot time showed the early fallout within the hundred milliroentgen per hour at 12-hour line to be fairly well verified, at least in the direction in which it went. Again they did not get the curvature of the later fallout.

Chairman DURHAM. What would be your observation as to the accuracy there in the predictions by the Weather Bureau and the other outfit? It looks to me they are off quite a bit in the prediction, because the observation line there cuts back pretty quick, and the other continues on up.

Dr. KELLOGG. The early part, as I say, in both cases was fairly well verified, but neither of them anticipated the shift of the wind which occurred later on. I think this is what one would expect. The meteorologists don't fool themselves as to how well they can predict the wind. There are a number of studies of this matter. One of the best ones recently was by the Air Weather Service, which gives actual wind statistics and forecast statistics. Recently, Jack Reed, a meterologist with the Sandia Corporation, has made a study of this situation and applied it directly to Nevada, the purpose being to try to assign some kind of probability to a forecast made a certain number of hours before shot time. Meteorologists recognize that any forecast is a kind of probability. It is an educated guess. This effort by Reed is a very noble effort to actually assign the right kind of probability to such a forecast, so that the people who have to use the forecast can know with what certainty the forecast was made.

Representative COLE. How do you account for the fact that the forecast of the direction of the fallout was reasonably accurate, but the forecast of the breadth or width of the fallout was quite inaccurate?

Dr. KELLOGG. I don't know the details. I did not sit down and go through exactly the assumptions that were made in each of these models by these people. I can only say that it would have something to do with the model they took, that is: How big a cloud they assumed, which would determine how wide the pattern was; how the radioactivity was distributed with height; the fraction which fell out, which we were talking about earlier—any of these might not have been predicted accurately. As I mentioned earlier we are uncertain about this fraction when we are firing in a tower. Any of these assumptions could have had an effect on the width of the predicted pattern.

Representative COLE. But the analyzers did know in advance the estimated yield of the test, did they not?

Dr. KELLOGG. Yes. Even though you may know the yield for a tower shot, you may not know the fraction of this yield which takes place in the early fallout with any accuracy, nor how it is distributed with height and particle size. These could have accounted for this changing shape.

Representative VAN ZANDT. Both groups had the same data as far as weather was concerned in that part of the world.

Dr. KELLOGG. Yes. They both used the same wind prediction.

Chairman DURHAM. In other words, they are pretty good up to a hundred miles, but beyond that it is not too accurate?

Dr. KELLOGG. That is the way it looks here, and that is the way it would always tend to look where we have a difficult forecast situation. This is probably a very light wind condition. The distant parts are really rather unimportant. I might mention here, as I recall, that the farthest extension of the 100 milliroentgen per hour line on this chart represents a "lifetime dose"—that is, the accumulated dose you would receive if you stood out in the open from the time it came down to infinity—of 9 roentgens. At this point on the 10 milliroentgen per hour line it is much less. It is a fraction of a roentgen.

Representative HOLIFIELD. You have not given us the strength of that particular weapon.

Dr. KELLOGG. About 30 kilotons on a 500 foot tower.

Representative VAN ZANDT. Doctor, are you in a position to tell us how long you actually followed that cloud?

Dr. KELLOGG. I am sure it was followed. I don't remember the details. An attempt is made for radiological safety purposes to trace where the cloud went by meteorological analysis. This is something which we have done quite a bit of at Rand. I don't remember whether we analyzed this one particularly or not. It is possible to do it by just analyzing the winds. It is also possible to do it by monitoring it by aircraft.

Representative VAN ZANDT. Is that your field, monitoring the cloud by aircraft?

Dr. KELLOGG. No, that is not.

Representative COLE. Would you repeat the dosage at 10 miles out? Would you state again what that is?

Dr. KELLOGG. Let up put this first chart (p. 114) back up which has the scale of miles. Let me make sure I have the right numbers here.

This point here—the furthest extension of the 100-milliroentgens-per-hour, 12-hour line—represents an infinity dose of 9 roentgens. That is about 30 miles from ground zero.

Representative COLE. Tell me what you mean by an infinity dose of 9 roentgens.

Dr. KELLOGG. By reconstructing the pattern and also by certain instruments which note when the thing starts, we can tell when the debris arrives at the ground. It doesn't all arrive at once, but it arrives within a relatively short period of time. Then, if we had an instrument which just simply counted roentgens, and it was hung on a post 3 feet above the ground and stayed there from then to doomsday, it would fiinally accumulate 9 roentgens. That is what we mean by infinity dose. Of course, most of this 9 roentgens would be accumulated in the first few days.

Representative COLE. What is the influence which determines the period of accumulation other than wind?

Dr. KELLOGG. The wind determines when it starts. The total dose then depends on the amount which comes down, and when it came down.

Representative COLE. Suppose it got there at this point and there was no wind at all.

Dr. KELLOGG. It would hardly get there if there were no wind at all.

Representative COLE. I still do not understand what you mean by a 9 roentgen perpetuity dosage.

Dr. KELLOGG. I can draw it perhaps as a time plot. (At the blackboard). This is the dose rate in roentgens per hour on the vertical scale. Here is the time on the horizontal scale. We said this was for a point about 30 miles out from ground zero. Suppose there was a 10-knot wind, so about 3 hours after shot time we begin to get fallout. The dose rises at 3 hours, and suppose it falls for the next hour and then stops. That is probably what would have occurred, fallout occurring for about an hour while the cloud is passing by. Then decay starts. This is radioactive decay at the rate that Dr. Graves gave, according to the time-to-the-1.2 power law, where time is measured from shot time. If this were the rate at 3 hours, and if we go to 7 times that, or 21 hours, it would be down by a factor of 10. After another 7 times 21 hours, whatever that is, the dose rate would be down to a hundredth. If we counted up the total number of roentgens, that is, multiply the dose rate times the time for each time interval and sum over all the intervals, we would get a cumulative dose. If we calculated this out on the tail of the curve to an infinite length of time, we have what we call an infinity dose. As you can see from here, most of this infinity dose is obtained in the first day or so in this case.

Representative COLE. I think I understand. At least I do better than I did before.

Dr. KELLOGG. I admit it is a difficult concept at first, but it is one which the people who are working with fallout sometimes use. They prefer to use an infinity dose instead of a dose rate at some time. It is merely a matter of what you want to talk about.

Representative HOLIFIELD. Dr. Kellogg, how far are you on your summary? I understand that you can be with us tomorrow, and, if it is very long, I want to carry you over until tomorrow. If it is short, since it is 5:30 and the members have to get back to their offices——

Dr. KELLOGG. I would like to take a little bit longer, 10 or 15 minutes, if that is all right for you, so perhaps tomorrow would be better. What I have to present still, I think, is fairly pertinent.

Representative HOLIFIELD. We do not want to cut you out of any time. I suggest that we start with you tomorrow and, in the meantime, it will give the staff some time to look at your prepared presentation, and we may have some more questions for you.

Dr. KELLOGG. This was a good stopping point, anyway.

Chairman DURHAM. I might say this is my first lesson in meteorology.

Representative HOLIFIELD. The Chair will announce that the committee will resume its hearings tomorrow morning in room 457 in this building. There will also be a 2 p. m. session tomorrow. Wednesday, we will come back to this room again. The meeting stands adjourned.

(At 5:25 p. m., Monday, May 27, 1957, a recess was taken until Tuesday, May 28, 1957, at 10 a. m.)

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

TUESDAY, MAY 28, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION OF THE
JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to recess, at 10: 05 a. m., in room 457, Senate Office Building, Hon. Chet Holifield, chairman of the subcommttee, presiding.

Present: Representatives Holifield, Durham (chairman of the Joint Committee), Price, Dempsey, Van Zandt; Senators Pastore, Hickenlooper, and Bricker.

Present also: Professional staff members James T. Ramey, executive director; George E. Brown, Jr., Hal Hollister, staff technical adviser, and Paul Tompkins, consultant.

Representative HOLIFIELD. The committee will be in order.

Today we open our second day of the hearings on the nature of radioactive fallout and its effect on man. Yesterday we began our hearings with an introductory statement by Dr. Charles L. Dunham, Director of the Division of Biology and Medicine of the Atomic Energy Commission, in which he provided some perspective on the general radiation problem as a basis for the beginning of the hearings. He was followed by Dr. Mark Mills, associate director of the Livermore Laboratory of the University of California, who provided us with technical background information on radioactivity and radiation and the hazard aspects of controlled fusion and fission reactions.

Yesterday afternoon, Dr. Alvin C. Graves, chief of the testing operations of the Los Alamos Scientific Laboratory, provided more detailed information on the production of radiation and radioactivity by the detonation of nuclear weapons. He described the effects of immediate bomb detonations, together with local fallout and worldwide fallout. He also gave some indications of the nature of the fallout from so-called clean and dirty weapons.

Dr. Graves was followed by Dr. Frank Shelton, of the Armed Forces special-weapons project, and Gen. Alfred D. Starbird, Director of the AEC Division of Military Applications, who provided a few comments on Dr. Graves' testimony and the new book, The Effects of Nuclear Weapons.

Incidentally, General Starbird indicated that the printed statement entitled "Testimony Before the Joint Committee on Atomic Energy on the Production of Radiation and Radioactivity From Nuclear Weapons—Topic V" was his statement, which he submitted for the record. The chariman and committee were under the impression that

this statement, distributed prior to Dr. Graves' testimony, was the testimony of Dr. Graves, since they were somewhat similar. We were given a carbon copy of the statement which Dr. Graves used as a basis for his oral presentation, and are having it reproduced for the information of the subcommittee. It is hoped that the Commission will identify their statements in a better fashion hereafter.

Our last witness yesterday was Dr. W. W. Kellogg, of the RAND Corp., who began his testimony on the atmospheric transport, storage, and removal of particulate radioactivity, particularly local fallout debris.

Dr. Kellogg did not complete his testimony yesterday, and we are happy to have him with us again today to resume his testimony.

Dr. Kellogg, will you please come forward? You may proceed where you left off:

STATEMENT OF DR. W. W. KELLOGG, OF THE RAND CORP.—Resumed

Dr. KELLOGG. Mr. Holifield and members of the committee, perhaps I should start by recapping just very briefly what happened yesterday, and perhaps making it a little bit clearer. I would like to very briefly mention the fact that the scientists who have been interested in studying fallout have been in fairly close touch with each other, and last March about 60 of us assembled in Santa Monica, Calif., to try and iron out some of the points of difference that we had.

Chairman DURHAM. You say 60 people, Doctor. Whom do you mean?

Dr. KELLOGG. Sixty people representing the various agencies, such as the AEC, the Air Force, the Army, the Navy, and various civilian agencies who have all been connected in one way or another with studies of fallout.

Chairman DURHAM. Was there a report made by that group?

Dr. KELLOGG. The report is being prepared. It will be classified when it comes out, because we wanted to discuss specific tests. Therefore, it is classified. However, there was one thing which we could all agree on at the end of the session, and that was that we had a long way to go before we could all get a consistent and clear picture of this process of radioactive fallout.

In particular, I think it should be mentioned that the fraction of fallout from a surface burst, which I gave yesterday as around 80 percent, in my opinion, was discussed at great length at this meeting, and it was shown that the evidence which we have for this fraction which falls out from a surface burst is not clear, and that we really are not certain about the fraction which falls out. We know that it is roughly 50 percent, plus or minus some number of percent, and the 80 percent which I gave you is sort of a best guess that RAND has made. I do not think that I should say this is a certain number by any means. I wanted to make that clear.

Representative HOLIFIELD. The 80 percent goes into the stratosphere?

Dr. KELLOGG. The 80 percent is what falls down in the first 24 hours or so. It would leave 20 percent to stay in the air.

Representative HOLIFIELD. This only refers to bombs, where the column does not go into the stratosphere?

Dr. KELLOGG. No, sir. This is more or less independent of yield, I would say. We have an observation of a low-yield weapon, and we have some other observations of higher yield weapons; and the fraction which falls out in early fallout does not seem to be very sensitive to yield.

I think the important difference, and one which I think will be taken up by Dr. Machta, who is following me, is that when we have a low-yield weapon the cloud does not go very high; therefore what is left is at a relatively low level in the troposphere, which is the lower part of the atmosphere. When we have a high-yield weapon, then what is left is higher in the atmosphere, in the stratospere.

The fraction of the debris taking part in the close-in fallout depends on whether it was a surface burst or not. How high it goes depends on the yield.

Representative HOLIFIELD. For the purposes of clarification, will you please explain what you mean by the troposphere?

Dr. KELLOGG. Yes, sir. The troposphere in middle latitudes where we are now is the atmosphere from the ground up to about, say, 30,000 to 40,000 feet. It is the part of the atmosphere that contains clouds, contains the weather as we know it.

Representative HOLIFIELD. And in the Tropics, it would go up to about 50,000?

Dr. KELLOGG. 50,000 to 60,000 feet in the Tropics; yes, sir.

Representative HOLIFIELD. And above that is the stratosphere?

Dr. KELLOGG. That is right.

I will not belabor this point. I just wanted to indicate there is some uncertainty about this number.

Yesterday we showed charts from the May 5, 1955, open shot in Nevada, a shot of roughly 30 kilotons on a 500-foot tower. The motive for showing the fallout from this particular burst was to give the committee a little bit of feel for the irregularity of one of these fallout patterns, and to show that various ways of predicting the fallout had been developed; that the predictions close in where the fallout is heavy enough to be important is fairly accurate, whereas further out, where the fallout is relatively unimportant the predictions are less certain.

I think in Nevada the fallout patterns are particularly irregular because of the terrain features which break it up. The rugged terrain also makes it hard to observe the fallout pattern.

So the red line which I showed on that chart representing the "observed" fallout is only roughly known. If we had a complete map, we would see it marching up across the mountains and down into the valleys, and we know these have an effect upon fallout. It would not be a smooth line as I showed it.

Representative HOLIFIELD. Would you say the area is such adjacent to the explosion point of these weapons to give the maximum opportunity for local fallout?

Dr. KELLOGG. That appears to be the case; yes, sir.

The hundred milliroentgen per hour line at 12 hours, which was shown on the chart, only went out about 30 miles in a due-north direction, and this early fallout, of course, can be forecast fairly well.

There are two further topics which I would like to take up, which I did not have a chance to yesterday.

One has to do with the growth of the pattern in time. I think we have not really discussed the growth in time of the pattern. We have

tended to look at these patterns as if they were laid on the ground with a big rubber stamp, whereas I think you all understand that the pattern develops over a period of time because the debris arrives at different places at different times in a more or less orderly process.

In particular, the question of when the fallout occurs close in to ground as zero, I believe, requires a little bit of attention, since in an emergency this would have an important bearing on what plans one would take to get out of the fallout.

In preparation for this hearing I collected all the data I could get from the tests which had a bearing on this question of when the fallout begins relatively close in to ground zero; and by relatively close in, I do not mean just a few thousand feet. I mean at distances ranging from 8 to, say, 30 miles, from ground zero for large yields, where the atomic cloud is quickly overhead. That is, this is the fallout which is in the shadow of the mushroom cloud.

It appears from a collection of data, which are summarized in the report which I presented for the record, that the fallout close in does not generally begin for about 30 minutes. The times of arrival actually vary from 20 to about 40 minutes. I think this is significant, and I think the explanation is rather easy to see. If one visualizes the fact that most of the debris is carried up in the mushroom cloud, then when the mushroom cloud stabilizes it takes a while for this material to get back down to the ground. So this delay seems reasonable, and I have documented it with the data which we have from the atomic tests.

The second part, having to do with the growth of the pattern in time, I think, can best be illustrated by this chart which, incidentally, is taken from the unclassified article in the Journal of Meteorology, written by Dr. Rapp, Mr. Greenfeld, and myself. So this is familiar to meteorologists who have read the journal article.

This chart shows a succession of fallout patterns at various times: First, a half hour, 1 hour, 2 hours, and 6 hours. It is from a 1-megaton explosion, and it is assumed there is two-thirds of a megaton of fission products represented in this fallout pattern. (See p. 116.)

The dose rates represented are in roentgens per hour at the time of the pattern.

I believe this is instructive in showing the way in which the pattern grows, in showing that it is most intense when it first comes down, and then decays after it is on the ground.

Close in we have the inside line, the thousand roentgens per hour at a half hour. The next line is 500. In other words, judging from the numbers which we heard yesterday, if this dose were to be imagined to be steady, at roughly half hour you would get a lethal dose in something like an hour.

Representative HOLIFIELD. For how many miles?

Dr. KELLOGG. The scale of miles is here. The 500 roentgen line at a half hour extends out, I would judge, about 12 miles.

Representative HOLIFIELD. In other words, in one-half hour everything within 30 miles downwind—is it 12 miles or 30 miles?

Dr. KELLOGG. Twelve miles.

Representative HOLIFIELD. Twelve miles downwind would receive a lethal dose of 500 roentgens?

Dr. KELLOGG. Yes.

There is one thing which was not taken into account in this calculation because it was done before we had really studied the time-of-arrival business. It appears that at about half an hour this blanket of fallout material descends on the ground, and so that at half an hour it is sort of nip and tuck whether the fallout has arrived yet or not. This half-hour picture might really refer to something like 40 minutes, but I do not think we know enough to make a clear distinction.

Senator BRICKER. What about the wind currents at that time?

Dr. KELLOGG. The wind current was a fairly strong west wind, and the wind did not change much with altitude in this case. So it is being laid out in an easterly direction at a fairly rapid clip.

Senator BRICKER. What do you mean by "fairly strong" winds—20 miles?

Dr. KELLOGG. In the original article there is what we call a hodograph showing the winds. I did not reproduce it on the chart, and perhaps I should. I can tell you roughly what they were.

Senator BRICKER. That is what I want, just roughly.

Dr. KELLOGG. They roughly range from about 40- to 80-knot winds in this case. Fairly windy day at high altitudes.

Representative HOLIFIELD. Would you explain at this point why you have on the chart there "1 megaton yield" and then "two-thirds megaton fission yield"? Would you give us a clarification on that?

Dr. KELLOGG. This represents the fact—and it is merely for illustration purposes only, of course—that this was a thermonuclear device in which part of the yeld came from the thermonuclear reaction.

Representative HOLIFIELD. Part of the blast yield?

Dr. KELLOGG. Part of the blast yield.

Representative HOLIFIELD. Or the heat yield?

Dr. KELLOGG. That is right.

Representative HOLIFIELD. Therefore, you figure roughly you would lose a third, that the megaton would not be completely a 1 megaton of fission?

Dr. KELLOGG. That is right.

Representative HOLIFIELD. One megaton of radioactive fission, but it would be two-thirds of a megaton in the fission products, and the other third in blast and heat?

Dr. KELLOGG. No, sir, that is not quite the way to say it, sir.

The total energy yield and thermal yield in terms of the work put out by the explosion was 1 megaton. However, only two-thirds of a megaton of fission products were released. And the conversion there from megatons of work to megacuries is the thing which Dr. Graves discussed yesterday, how to do this. As I say, this is for illustration only.

Representative PRICE. Mr. Chairman?

Representative HOLIFIELD. Mr. Price.

Representative PRICE. You will probably cover this before you get through with the chart. With an increasing yield, how does the figure over there on the half-hour basis expand, or how does this work if you drop a 10-megaton bomb?

Dr. KELLOGG. The way in which this pattern changes with yield, seems to be in such a way that the area within any one of these contours goes up with the yield. The areas go up linearly with the yield.

Representative PRICE. What would that 500 figure be on a 10-megaton bomb?

Dr. KELLOGG. There would still be a 500 line on the 10-megaton bomb, but it would be 3 times bigger in any dimension. It would have an area 10 times bigger.

Representative PRICE. It would have an area, say, of about 40 miles?

Dr. KELLOGG. Yes; that is about right. I would rather point to the 1-hour pattern because there is a question as we raise the yield, this question of whether this material gets back down to the ground in half an hour. I expect it would not for a 10-megaton yield. It probably would for 1-megaton yield. That is because of the difference in altitude.

Let's look at the 1-hour pattern, and talk about that. I prefer that to the half-hour pattern, particularly if we wish to discuss the way in which it scales with increasing yield.

Representative PRICE. On the 1-hour one, you have 500 roentgens still extending pretty close to 12 miles?

Dr. KELLOGG. Yes; it is. It looks like it was about 10 miles.

Representative PRICE. So, if you had a 10-megaton drop, the 500-roentgen area would be at least 40 miles?

Dr. KELLOGG. That is true; yes. The square root of 10 is a little over 3.

Representative HOLIFIELD. Now, in areas in the case of warfare where cities are close together that are primary targets, you would also face the factor of lapping, would you not?

Dr. KELLOGG. Yes.

Representative HOLIFIELD. And that would increase the radioactive fallout to the extent that the degrees of lap would add?

Dr. KELLOGG. That is true.

If I may, I would like to show a chart in which the fallout from a multiple-bomb campaign is shown. (See p. 119.)

Dr. KELLOGG. Now that we have had time out for the scene moving, I would like to say that this chart was prepared by Mr. Charles Shafer of the Federal Civil Defense Administration headquarters in Battle Creek, Mich., and he has very kindly let me borrow this chart, which was prepared for the FCDA's Operation Sentinel.

Representative HOLIFIELD. Would you make an estimate as to the pictorial authenticity of this, based upon scientific information?

Dr. KELLOGG. Yes. This kind of a fallout chart has been done as an exercise many times.

Chairman DURHAM. It was actually——

Dr. KELLOGG. Mr. Shafer is in the audience, and if you press me on the details, I will perhaps ask permission to have him help me.

Representative VAN ZANDT. It would be nice to have Mr. Shafer up here.

Representative HOLIFIELD. Yes, let's have Mr. Shafer up here at this time.

Dr. KELLOGG. Fine. I would like very much to have him up here.

Representative HOLIFIELD. Mr. Charles Shafer. We are happy to have you before the committee this morning. The committee would like to hear briefly the substantiation from a scientific standpoint of this chart which you have prepared, and its meaning.

STATEMENT OF CHARLES SHAFER, METEOROLOGIST, UNITED STATES WEATHER BUREAU (ON ASSIGNMENT TO FCDA) [1]

Mr. SHAFER. This particular fallout analysis is purely hypothetical, which is obvious. It is based upon one of the techniques which Dr. Kellogg explained to the committee yesterday, the stylized pattern technique, and it is virtually identical to that which is described in the AFSWP paper, copies of which were entered into testimony yesterday.

The meteorology used on this particular fallout analysis was the wind existing from 80,000 feet altitude, down to the surface of the earth during the period November 20 to 21, 1956.

In actuality, if such an attack or an attack of this magnitude——

Representative HOLIFIELD. Will you please repeat the date? Some of us did not hear that.

Mr. SHAFER. November 20 to 21, 1956, a 24-hour period.

This represents an attack of total yield of approximately 2,500 megatons, a very large attack. It is an estimate. It is an analysis based upon many assumptions such as Dr. Kellogg described yesterday. In an actual attack of this magnitude, certainly the levels of radiation would vary considerably from those indicated on this chart, simply because we do not know all of the information we need to know in order to do such an analysis as this is on a forecast basis.

Representative VAN ZANDT. What type of attack was it?

Mr. SHAFER. This was an attack of thermonuclear weapons.

Would you like to have some information on the size and the distribution of weapons?

Representative VAN ZANDT. As long as you do not enter the classified field.

Mr. SHAFER. There is no classification involved in it.

The weight and distribution: The weapons were of three sizes: In the range of 5-megaton yields; 10-megaton yields; and 20-megaton yields. There were 250 bombs, with a total yield of about 2,500 megatons. There were 144 areas of attack. Fifty-three of the areas were basically population and industrial centers; 59 areas were basically military installations; and the remaining 52 areas contained both military and population objectives.

Representative VAN ZANDT. How many minutes or hours were involved?

Mr. SHAFER. In the attack?

Representative VAN ZANDT. Yes, in the attack.

---

[1] Waverly, N. Y., graduated from State Teachers College at Albany in 1939 and did graduate work in mathematics and meteorology at American University and New York University.

Assigned to Federal Civil Defense Administration by the Weather Bureau in April 1955 to assist in radiological defense problems resulting from phenomena of fallout. Began meteorological career as weather observer at Raleigh, N. C., prior to World War II. Flight weather forecaster at Dayton Army Air Field and consultant to Accelerated Service Testing Branch of U. S. Air Force. One year scholarship at College of Engineering of New York University. Subsequent to this Mr. Shafer was detailed to International Civil Aviation Organization at Montreal for a special research project, then to Washington National Airport as an international forecaster.

Next he was assigned to Weather Bureau-Air Force-Navy Analysis Center and in 1952 was loaned to CAA and transfered to Europe to plan and supervise the rehabilitation of the Greek Weather Service. In 1954 Mr. Shafer received 3 months of specialized instruction in long-range forecasting and worked as supervising meteorologist at the Military Weather Bureau unit at Suitland, Md.

Mr. Shafer transferred from the Weather Bureau to the Radiological Defense Operations Office of FCDA and will work with other governmental agencies in developing a national radiological monitoring network. (Submitted by Federal Civil Defense Administration.)

Mr. SHAFER. Approximately 2 hours for the delivery of the attack, sir. The fallout analysis was carried on for 24 hours. We assumed that there was sufficient fallout debris to render the analysis valid to carry it out for 24 hours.

One thing I should mention is that the analysis of the east coast is probably erroneous. It would have been better to have terminated the line at the coast, simply because debris in the ocean area is subjected to considerable mixing by ocean currents, and there would have been considerable dilution. However, from our analysis this is an indication of what would have come down. It would not have remained in that location, as it would have been more apt to do on the ground.

Representative VAN ZANDT. Will you mention some of the targets, and give the geographical distribution of them.

Mr. SHAFER. Yes. We gave the Air Defense Command credit for quite a few knockdowns on this. This represented the results of the aircraft which were able to penetrate our borders and deliver their weapons as indicated.

The heaviest concentration, the heaviest complex of detonation happens to be in the Detroit area, because we made some assumptions not only with regard to enemy intent in getting to target, we also assumed there were some knockdowns of aircraft and some unintentional weapon detonations.

In the Detroit area, for example, there are some 70 or 80 megatons of detonation of weapons within 15 or 20 miles of one another. Consequently, there is a tremendous overlap from Detroit eastward across Buffalo and across central New York State—the factor Mr. Holifield mentioned a while ago, the factor of overlap.

Chairman DURHAM. What is the yellow?

Mr. SHAFER. The yellow shading, sir, represents the areas of most intense radiation hazard, and area where the dose rate normalized back to 1 hour after detonation would have exceeded 3,000 roentgens per hour.

The red areas are where the radiation levels would have exceeded 1,000 roentgens per hour. The blue areas are where the radiation levels would have exceeded 100 roentgens per hour. The green levels are where the radiation would have exceeded 10 roentgens per hour.

Would you be interested in the effects of this particular attack as far as people are concerned?

Representative HOLIFIELD. Yes. What was your estimate on the loss of human life?

Mr. SHAFER. May I read that, sir, so I will have it correct?

Without evacuation of the target cities to escape primary weapons effects—that is, to escape blasts, thermal and initial radiation effect——

Representative HOLIFIELD. I did not get that.

Mr. SHAFER. Without target evacuation, target area evacuation to escape primary weapons effects, and assuming present-day shielding which exists in the United States, that is, homes, or home basements, or the basements of large administration buildings, the bomb-damage assessment on this particular attack indicated a total loss by death of about 82 million people, based upon current United States population, and about 24 million surviving casualties, 60 days subsequent to the attack. This left about 60 million relatively uninjured, but doubtlessly suffering some radiation effects.

In this particular analysis, we only carried it down to the 10 roentgens per hour. So that even in the white areas, where the levels are relatively low, there could be some radiation effect. Of the total fatalities, some 50 percent were a result of radiation factors.

Now, by assuming a 50-percent effective evacuation of the target areas——

Representative HOLIFIELD. At that point I think you should tell us where you have your evacuation centers.

Mr. SHAFER. On this first analysis, in which there were about 82 million fatalities, there was no evacuation assumed, simply a duck-and-cover operation upon the sound of the warning bell that an attack was imminent.

Representative HOLIFIELD. All right. Now, you are going to assume evacuation. Where are you going to evacuate them to, under the same conditions, to protect them from fallout on a map of that type?

Mr. SHAFER. We had to make two assumptions on this particular phase of the analysis.

Assuming a 50 percent of effective evacuation beyond the D zone of blast damage, that would be from 5 to 15 miles beyond ground zero, depending on weapon size; assuming a 50-percent effective evacuation, and assuming the existence of a radiation shelter program in the United States, assuming the existence of shelters to which evacuees could go, the fatalities decreased to about 31 million. So there was a net saving of over 50 million people under a radiation shelter program, and an assumption of 50 percent effective evacuation beyond the primary effects of the weapon.

Senator PASTORE. And that hypothesis is predicated upon an attack of 2,500 megatons within a period of 2 hours, and you are talking about evacuees within that period?

Mr. SHAFER. The evacuation immediately prior to that, sir. Evacuation beyond the D zone of blast damage. Evacuation for, perhaps 5 to 15 miles to shelters prior to the attack, perhaps 1 hour, or perhaps less than 1 hour prior to the attack.

Representative HOLIFIELD. Of course, you have not only made two assumptions which cannot obtain under present conditions, one, because you do not have a warning time; two, because you do not have a shelter system; but you made a third assumption that you know where point zero of the falling bombs is going to be. All three of those assumptions are in the realm of impossible prediction.

Mr. SHAFER. Actually, in the analysis, we only assumed a 50-percent evacuation of the target areas attacked in this particular exercise; that is correct.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. In 2 hours' time how many bombs were dropped.

Mr. SHAFER. 250 bombs on 144 areas.

Representative VAN ZANDT. 144 areas?

Mr. SHAFER. That is right.

Representative VAN ZANDT. Your chart indicates that they dropped bombs on the Northwest?

Mr. SHAFER. That is correct, sir. Seattle——

Representative VAN ZANDT. And California?

Mr. SHAFER. Correct.

Representative VAN ZANDT. And then moved east. How about Arizona and New Mexico?

Mr. SHAFER. Yes, sir. We have weapons detonated at Phoenix, at some of the airbases near there, and at Tucson.

Representative VAN ZANDT. How about the Salt Lake City and Denver areas?

Mr. SHAFER. That is correct, sir. Hill field in Utah, and also Salt Lake City itself, sir. And Denver, at the airbase outside of Denver, and Denver city itself.

Representative VAN ZANDT. In other words, you covered all the densities of population in the United States?

Mr. SHAFER. Many of them, that is correct.

Representative VAN ZANDT. Whether military or otherwise?

Mr. SHAFER. Military, civilian, and industrial targets were the primary objectives. However, there are some random detonations also at areas that would not meet those criteria.

Representative VAN ZANDT. You said 50 percent of the casualties could be charged to radiation?

Mr. SHAFER. That is correct.

Representative VAN ZANDT. Are we to assume the other 50 percent were killed by blast effect?

Mr. SHAFER. That is correct, blast and thermal effect.

Representative PRICE. Mr. Chairman?

Representative HOLIFIELD. Mr. Price.

Representative PRICE. What type of bombs were you assuming?

Mr. SHAFER. Thermonuclear-type weapons, and obviously they were not the relatively clean type of which you were speaking yesterday.

Representative PRICE. Exclusively H-bombs?

Mr. SHAFER. That is correct.

Representative VAN ZANDT. In your imagination, did you provide for an aerial burst?

Mr. SHAFER. These are all surface detonations.

Representative VAN ZANDT. All surface detonations?

Mr. SHAFER. Yes. You will notice there is quite a variation of the pattern since we used the actual existing meteorology of a particular day.

For example, in Florida the winds were much less strong, than over here [indicating], say across Colorado and across the northern plains. As I recall the wind speeds in the Florida peninsula were in the matter of the neighborhood of perhaps 15 miles per hour, the mean effective wind from 80,000 feet to the surface, whereas they exceeded 50 miles per hour as we went further north.

Representative VAN ZANDT. What period of time did the deaths occur?

Mr. SHAFER. The first 60 days. Our computations went for the first 60 days, sir. There may have been some deaths beyond then, because, as pointed out yesterday, the delivery of radiation exceeds 60 days. However, certainly the bulk of the problem would be indicated.

In this particular exercise we dealt only with the immediate survival problem. We did not take into account the soil contamination, the uptake of strontium 90, and the long-term haul problem that certainly would be very much with us from an attack of this magnitude.

Chairman DURHAM. How about water? Did you take that into consideration?

Mr. SHAFER. No, we did not take contamination of water into account here. Certainly there would be considerable contamination of reservoirs from fallout, from rainfall, moving the deposition from its point of contact and into reservoirs.

Representative HOLIFIELD. You might say, then, this represents the immediate effect, say, the within-24-hour effect?

Mr. SHAFER. As far as this analysis of the fallout is concerned; yes. The mortality of fatality statistics which I gave you indicated the first 60 days.

Representative HOLIFIELD. Yes.

Mr. SHAFER. As far as contamination of water is concerned, certainly southern Lake Michigan would have had a considerable amount from this. Many cities depend upon their drinking water from Lake Michigan.

Senator PASTORE. It is my prayer that these questions always remain hypothetical, but why did you take the figure of 2,500 megatons?

Mr. SHAFER. Solely to study the problems connected with a large-scale attack with ground-burst weapons. There is nothing significant about the figure 2,500. This is one of an infinite number of attacks which could have been assumed. I might advise the committee that we have studied attacks with much less and much greater megatonnage than this. We recently completed an agency exercise based upon a 20-megaton surface detonation on all of the 314 targets in the United States. The megatonnage was some 2½ times that indicated on this analysis, but it was very specialized. It was certainly a situation that no enemy would be able to accomplish, to get 314 intended weapons upon their intended targets.

Representative HOLIFIELD. This, of course, does not give us an estimate of the amount of radiation that would go into the world's atmosphere and stratosphere, and which would fall over the following 10 years around the world on areas which are not attacked by an immediate detonation of weapons?

Mr. SHAFER. That is correct, sir.

Chairman DURHAM. Then it was assumed in the preparation of the map that this could be accomplished in the 1960's?

Mr. SHAFER. This was not intended to represent capability at any particular time, although we assumed that such an attack could be increasingly within enemy capability during the 1960's.

Representative VAN ZANDT. Was it based on the Russian capabilities?

Mr. SHAFER. This was based solely upon our assumption for this exercise.

Representative VAN ZANDT. Was it based upon Russia's capability of getting 100 percent of her planes through to the target?

Mr. SHAFER. No, sir. We assumed that this represented those aircraft which were able to penetrate our borders and deliver their weapons, 250 weapons. I do not know how many aircraft that would require. If the Air Defense Command were effective in knocking down 50 percent of the invading bomber aircraft, this would imply 500, perhaps, in the original attack.

Representative VAN ZANDT. Would you take a bomb burst over Los Angels, and trace it as it moves east, giving us some idea of the destruction in human lives?

Mr. SHAFER. That would be rather difficult, but I will attempt it, sir.

There were four weapon detonations in the vicinity of Los Angeles, the large area, the large population center, the country. The blue-dashed line at the end of my pointer represents the area which would be affected by fallout at the end of 1 hour. That is 1 hour subsequent to the detonation. The levels in the yellow area would exceed 3,000 roentgens per hour. Unless survivors in that area had very good shelter, shelter with a shielding factor of perhaps 5,000, everyone would be dead. It would be a writeoff area.

Almost the same generalization in the red area. Not so much in the blue. Certainly not in the green. And when we get out to the white, a relatively no-hazards area at all.

By the end of 3 hours, the debris would have moved down almost to the extreme southeastern portion of California, almost to the Colorado River, the border between Arizona and California. By 7 hours, it would be over to central Arizona. However, at this time you would have to decrease the levels of radiation indicated on here by a factor of 10, as was mentioned yesterday, the radiological decay, the radiation decay which takes place. So by this time, in the yellow areas the dose rates are no longer 3,000 r per hour, but are down to 300 r per hour. In such a field as that, one could still be exposed to a lethal dose in less than 2 hours' time.

The debris spread on eastward to New Mexico by about 12 hours. However, by this time there have been considerable overlaps from attacks on San Diego, and from attacks on Arizona; so it becomes rather impossible to trace the debris from one single bomb.

Here is one [indicating] in the data which can be traced a bit more easily. This represents 6 hours of time; some 12 hours down to Grand Canyon; 18 hours, perhaps, over to the Colorado border; and by 24 hours into the Denver area. But it would be of no significance at Denver, since Denver has been struck by 3 weapons some 24 hours before, and the addition at this time is a relatively no additional value. Is that what you wanted, sir?

Representative VAN ZANDT. That is it; thank you.

Representative HOLIFIELD. Mr. Shafer, will you please give us your background, whom you work for, and so forth, so we can have that on the record?

Mr. SHAFER. Yes, sir. I am a meteorologist from the United States Weather Bureau. I have been assigned to FCDA, the Federal Civil Defense Administration, for the past 2 years, to assist them in their radiological defense problem.

Representative HOLIFIELD. How long have you been in this work?

Mr. SHAFER. In the Weather Bureau?

Representative HOLIFIELD. Yes.

Mr. SHAFER. I have been in the Weather Bureau 16 years, sir.

Representative HOLIFIELD. In presenting this, do you feel that this is supported by a majority of the meteorologists; that this sort of a hypothetical portrayal would be supported by most of them?

Mr. SHAFER. Most of them would not take strong exception to this. As indicated yesterday, there are 4 different techniques, or ways of

doing this, and each of the 4 yields some minor variation. As far as presenting the magnitude of the problem, and, for planning purposes, to indicate what we are up against, this is reasonably accurate. For actual operations in the event of an attack, for actual survival operations, this would not be adequate. We could only accomplish an analysis such as this by complete monitoring or by a combination of monitoring and meteorological techniques.

Representative HOLIFIELD. Are there any further questions?

Thank you very much, Mr. Shafer.

Mr. SHAFER. Thank you, sir.

Representative HOLIFIELD. Dr. Kellogg.

Dr. KELLOGG. Are there more questions about this?

Representative HOLIFIELD. I think we will not need the charts.

Dr. KELLOGG. This closes my presentation. The analysis by Mr. Shafer was the last thing I wanted to present to the committee.

Representative HOLIFIELD. All right. Before you leave the stand, as an experienced student in this field, would you have anything to add to this presentation of Mr. Shafer on this particular point?

Dr. KELLOGG. No; I think he covered it very well.

Representative HOLIFIELD. From your scientific background and professional standing, would you concur, in general, with the remarks that he made?

Dr. KELLOGG. Yes. The techniques which he used are, I think, fairly well accepted by those of us who are planning fallout calculations.

Representative HOLIFIELD. Are there further questions of Dr. Kellogg?

Thank you very much, Dr. Kellogg, for your appearance before the committee. Your testimony has been very valuable.

Our next witness will be Dr. Lester Machta, of the United States Weather Bureau, and he will continue the testimony on atmospheric transport, storage, and removal of particulate radioactivity.

Dr. Machta has previously testified before congressional committees, and is looked upon as one of the real experts in this field.

STATEMENT OF DR. LESTER MACHTA, METEOROLOGIST, UNITED STATES WEATHER BUREAU [2]

Dr. MACHTA. Thank you, Mr. Chairman. I thank you for the opportunity of continuing the meteorological presentation. The story which I would like to tell pertains to a meteorological prediction of global fallout, and how this is verified by actual observation, and, finally, what this may mean for us in the future.

The radioactive debris which has not fallen out locally is carried by the atmosphere to distances far removed from the point of the

[2] Meteorologist, U. S. Weather Bureau; associated with atomic energy and meteorology since coming to Washington in 1948, now Chief of the Special Projects Section. Born in New York, N. Y., in 1919, graduated cum laude from Brooklyn College in 1939. His meteorological training includes graduate work at New York University (master of arts, 1946) and at Massachusetts Institute of Technology (doctor of science, 1948). During the war he taught meteorology in both a civilian and military capacity for the Air Force. Member of Sigma Xi, Pi Mu Epsilon, the American Meteorological Society, and the American Geophysical Society. Recently been given a gold medal for exceptional service by the Department of Commerce. Publications in the meteorological literature are numerous and, in recent times, include papers on atomic energy and meteorology. Has been a member of many important Government committees, including the Advisory Committee passing on the meteorological safety of tests in Nevada. Has been instrumental in making the worldwide measurement of radioactivity part of the International Geophysical Year program. (Submitted by U. S. Department of Commerce.)

explosion before entering man's environment or body. Why are we interested in the details of this transport? Aside from the academic meteorological implications, there are at least two aspects of atmospheric transport which are of importance to these hearings.

First, if the radioactive debris remains suspended sufficiently long, radioactive decay can reduce the hazard of the particles. Unfortunately, evidence points to residence times in the atmosphere which are too short to allow for appreciable decay of such substances as strontium 90 and cesium 137 with their 27- or 28-year half lives. Second, and more important, is the question of the uniformity or nonuniformity of deposition over the earth. We will return to this point later.

Senator BRICKER. Is the half life of cesium 137 practically the same as strontium 90?

Dr. MACHTA. I believe so, sir. The radioactive debris which has not fallen out locally can be carried either by tropospheric or stratospheric winds. I should like to show a number of placards.

The first placard (1) shows the earth as a sphere bounded by a layer of air in which our weather takes place, known as the troposphere; the upper layer, which is separated from the troposphere by the tropopause shown here as the line, is the stratosphere. The break in the tropopause in the area in which J appears is believed to be frequently associated with the jet stream, a current of high-speed west-to-east winds. The everyday weather—cloudiness, precipitation—occurs only in the troposphere. We are well informed about the tropospheric air motions, but know much less about the stratospheric air motions. Two features are, perhaps, of importance. First, there is considerable turbulence and, hence, mixing in the troposphere. On the other hand, the stratosphere is rather smooth and, as far as we know, much less vertical mixing takes place there.

Second, in both the troposphere and stratosphere, the prevailing winds blow from west to east or from east to west, so that the transport occurs much more rapidly in an east-west or west-east than in a north-south direction.

The fate of the radioactivity that is left over after local fallout has ceased depends upon whether it has been left behind in the troposphere or forced into the stratosphere. Thus, as has been mentioned many times, high-yield explosions with their tremendous force throw the mushroom heads into the stratosphere, while the lower yield tests such as we conduct in Nevada remain in the troposphere. High air bursts of almost any yield can throw their debris into the stratosphere, also.

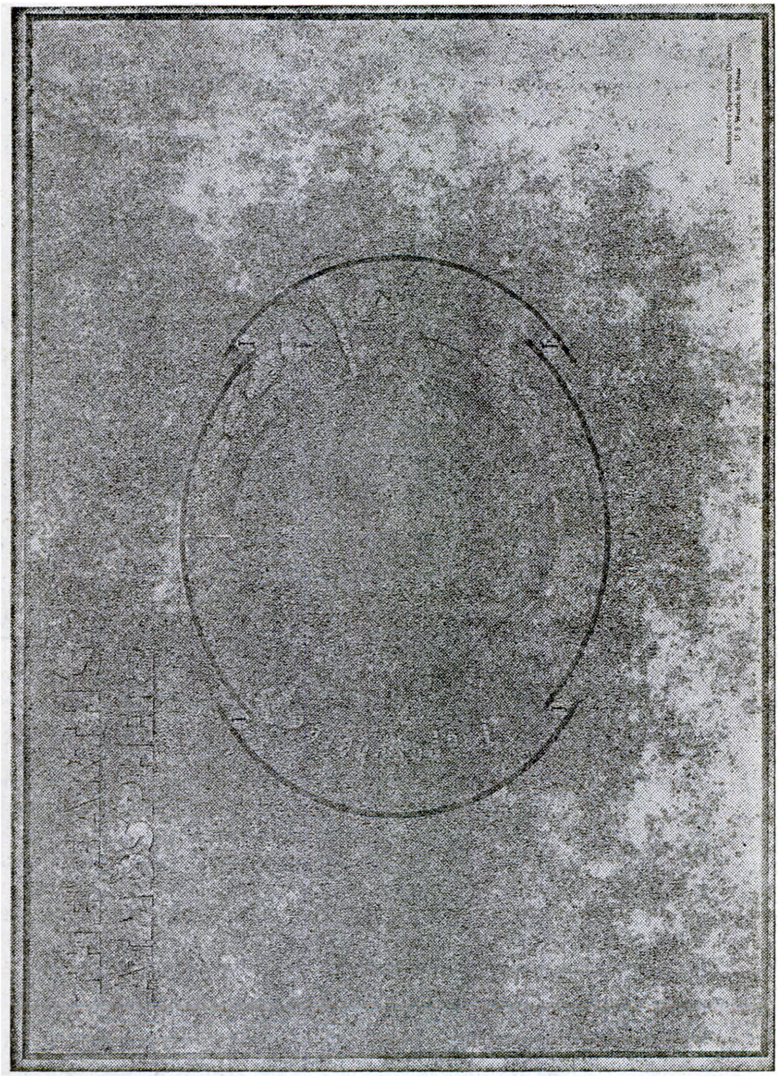

FIGURE 1

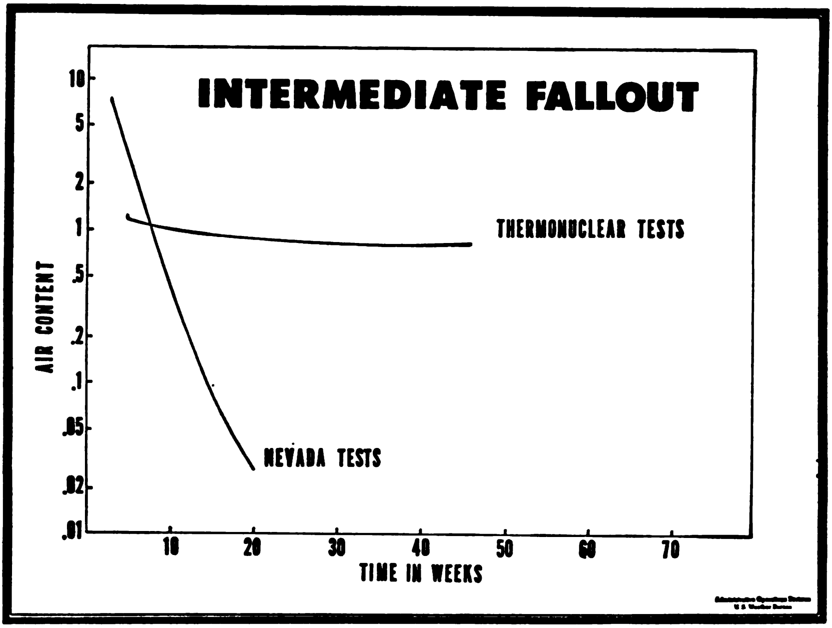
FIGURE 2



The next placard (2) shows the decrease with time of the atmospheric radioactivity from tropospheric and stratospheric sources. We see that for a Nevada A-bomb-type shot, in which air content is plotted against time in weeks after the explosion, the atmospheric radioactivity decreases rapidly with time after the test, so that within a matter of weeks, or at most a few months, the level of radioactivity is not appreciably above natural backgrounds. Precipitation and turbulence quickly remove the particles from the atmosphere. On the other hand, from the large-scale explosions, the thermonuclear tests, which throw their debris into the stratosphere, one finds practically no change with time. Although the same processes of removal are still active in the troposphere, the curve fails to show the decrease because there is a continual feeding of new radioactive debris from the stratosphere downward.

TROPOSPHERIC FALLOUT

Let us first look at the fallout from tropospheric debris. This placard (3) shows isolines of deposition from one of the Nevada test series. It is a Mercator map of the entire world, and the very heavy shading indicates the area around Nevada.

The brightness of the red coloring is proportional to the amount of fallout. I use the word "tropospheric" and "intermediate" interchangeably in this discussion. This picture illustrates the prevailing west-east flow by the fact that most of the radioactivity lies in the same belt of latitude as the original latitude of the explosion. The fallout is carried primarily to the east by the prevailing winds, and decreases in intensity as we get farther from the test site.

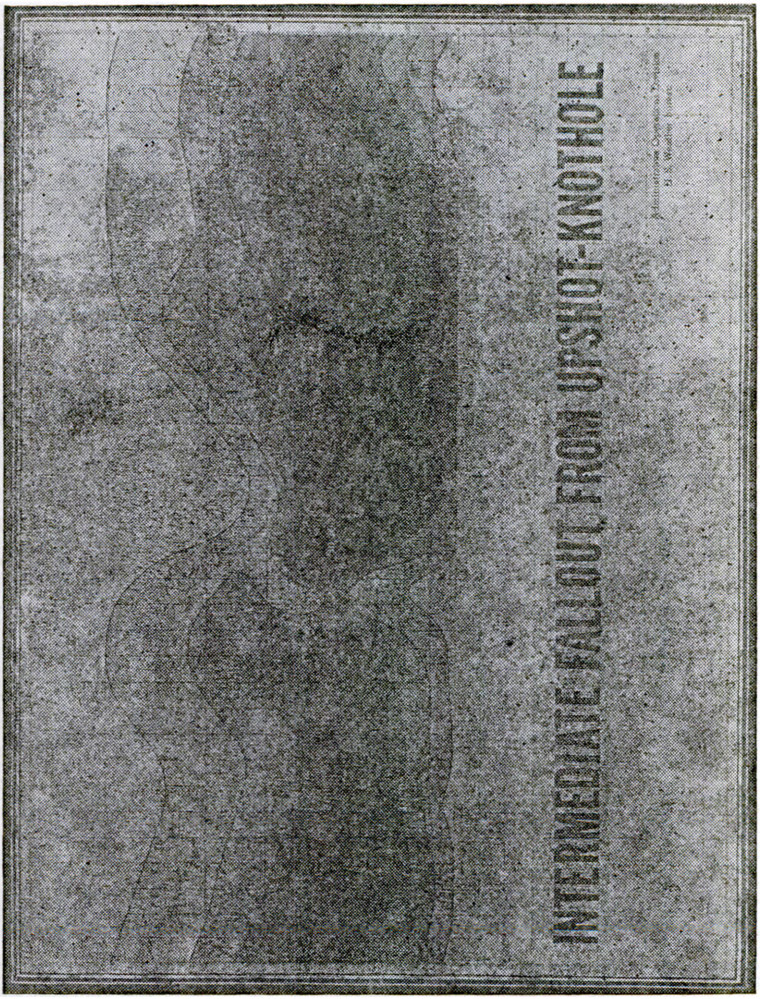


FIGURE 3

Representative HOLIFIELD. Before we leave that, Dr. Machta, I want to reread one of the lines you have given.

Dr. MACHTA. Yes, sir.

Representative HOLIFIELD (reading):

> This picture illustrates the prevailing west-east flow by the fact that most of the radioactivity lies in the same belt of latitude as the original latitude of the explosion.

Judging from the shading on your map there, and from this statement, then, there is a deposition in the Temperate Zone, assuming that is where these tests occur, where most of the people live, which is higher in intensity, although in different gradations, than it would be in either of the polar zones?

Dr. MACHTA. That is exactly correct, sir.

Representative HOLIFIELD. So when we talk about average global fallout, although it is a theoretical equation, it is an unreal evaluation in terms of the phenomena which actually occur?

Dr. MACHTA. I would like to take this up later. My main presentation actually deals with the nonuniformity of the fallout, and this is one of the aspects which gives rise to nonuniformity, namely, that the tropospheric fallout remains in the same latitude belt that the explosion takes place. But this is only one of the aspects.

Representative HOLIFIELD. My observation is, although it is only one of the aspects—my observation still is——

Dr. MACHTA. Is correct.

Representative HOLIFIELD. Is correct?

Dr. MACHTA. Yes, sir.

Representative HOLIFIELD. Thank you.

Dr. MACHTA. The next placard (4) provides the tropospheric fallout, the cumulative deposition for the first 35 days from the Castle-Bravo, the March 1, 1954, thermonuclear detonation in the Marshall Islands, showing once again that the fallout lies largely in the belt of latitude in which the explosion takes place. In the case of the large explosions, it is likely that the stem of the nuclear cloud provides most of the radioactive fallout in this period.

What fraction of the radioactive debris is deposited in the first few weeks or months—aside from the local fallout? For the typical Nevada tower shot, perhaps 75 percent, and for the high-yield ground explosion in the Pacific Proving Grounds, somewhere between 1 and 5 percent. These figures are very uncertain. Thus for the high-yield explosions, the delayed fallout is more important than the tropospheric fallout. This is because about 80 percent falls out locally, and when we add to this 5 percent more, we still have of the order of 15 to 20 percent, on the average, in stratospheric fallout that is still left after local and tropospheric fallout has ceased.

Thus, for the high-yield explosions, the delayed fallout is more important than the tropospheric fallout. It is evident that the tropospheric fallout is not uniform over the globe, as you just pointed out, sir.

STRATOSPHERIC FALLOUT

Finally, those particles which do not fall out locally or in the first 1 or 2 months, remain suspended in the atmosphere for a prolonged period—a matter of years, on the average. This has been termed

FIGURE 4

delayed or stratospheric fallout. These particles originate exclusively in the stratosphere. We do not know their size. The only thing we can say is that they must be quite small in order to remain airborne for such long periods of time. However, whether they are only carried downward from stratosphere to the troposphere by air motions or whether they also sink due to their weight, is not yet known for sure. From evidence I have seen, I would gues that there is a slow settling of the particles as fast as a mile or so per year—the principal removal is by downward atmospheric motions.

The radioactivity which is inserted into the stratosphere can be transported by 1 or 2 atmospheric processes; first, mixing, and second, direct transport. To understand these, consider an analogy—how a blob of ink in a bathtub can be transported, where the bathtub is considered to be the stratosphere. In mixing, one can imagine that the bathtub is stirred so that the ink quickly covers the entire water of the bathtub. In the second way, direct transport, one may imagine that a cup is dipped into the bathtub and part or all of the blob of ink is bodily lifted from one part and inserted into another part of the tub. It is quite evident that the first process, mixing, tends toward uniformity, whereas the second simply transports a blob from one place to another without materially changing the concentration. Our knowledge of the stratosphere is too limited to be sure of the comparative importance of these two processes. We are fairly sure that the vertical mixing—the exchange in the vertical—is very slow in the stratosphere due to the smoothness of the airflow.

I believe that the main movement of radioactive particles in the stratosphere is the result of direct transport. Mixing is so slow that the stratospheric distribution is nonuniform, even after 2 years.

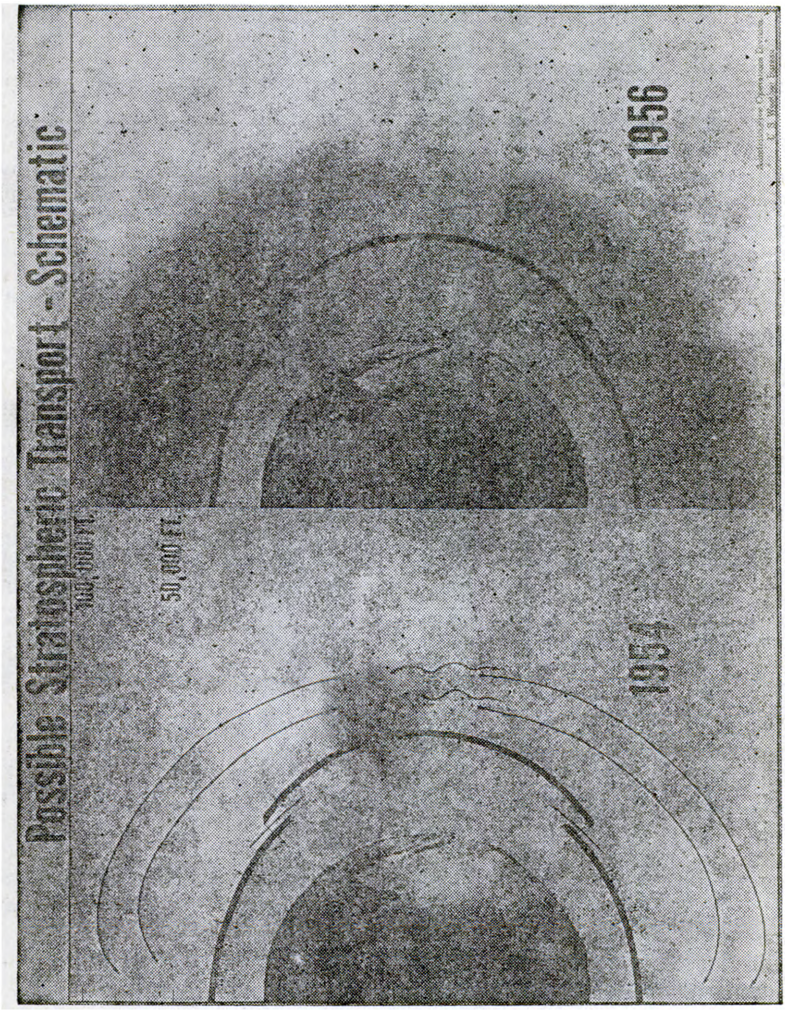
There are several meteorological hypotheses of direct transport or circulation in the stratosphere. I believe that a recent one proposed by Dr. Brewer of England best fits the facts available to me. Brewer is referred to as having said that there is—

> * * * slow poleward circulation of stratospheric air from the equatorial regions. During the course of this circulation, the air may be carried to heights of the order of 30 kilometers—100,000 feet—the height being greater in the winter hemisphere * * *.

The next placard (5) will show my interpretation of this circulation on the left-hand side. We see half of the globe and the tropopause as in earlier pictures. The H-bomb nuclear clouds in the Marshall Islands at 11° north, are shown schematically as one large red cloud. The wiggly arrows pointing southward indicate the possibility of southward mixing of a small part of the initial nuclear clouds into the Southern Hemisphere. In each hemisphere, we see the slow poleward circulation proposed by Brewer. I conclude that the bulk of the radioactivity in the stratosphere as in the Northern Hemisphere as illustrated on the right-hand side of the placard (5) by the heavy shading. The uncertainty in Southern Hemisphere stratospheric content is reflected by the question marks. I also believe that the bulk of debris is in the northern portions of the Northern Hemisphere rather than uniformly spread throughout the hemisphere.

Having now transported our radioactive debris to a different part of the stratosphere, let us ask where and how the debris may leave the stratosphere to enter the troposphere. Here, again, we have a

FIGURE 5



Possible Stratospheric Transport - Schematic
100,000 FT.
50,000 FT.
1954
1956

number of theories but no positive direct evidence. Ordinary vertical mixing processes will remove debris from the stratosphere through the tropopause and into the troposphere at all latitudes. However, it is believed that the break in the tropopause which one frequently finds in the vicinity of the jet stream, the region of very high west to east speeds in the temperate latitudes of both hemispheres, is a place of preferential exchange of air between troposphere and stratosphere. It is possible that it is in this area that much of the radioactive debris enters the troposphere. It has been also suggested that the formation of new and higher tropospauses, which may also occur with the passage of storms in the temperate latitude, will leave behind a considerable amount of stratospheric air to be incorporated into the troposphere. The tropopause of the polar regions of both hemispheres is often very indistinct, especially in winter and it has been suggested that removal can preferentially occur here. On the other hand, the equatorial tropopause is noted for its persistent intensity and a minimum of transport may occur through it. Meteorological theories, therefore, recommend more stratospheric removal in the temperate or polar than in the equatorial regions of the earth. The lengths of the arrows, which you see on the left-hand side of the placard (5) across the tropopause and through the tropopause break suggest the relative removal rates.

Once radioactive particles enter the troposphere, their stay is short. The ordinary weather processes and settling out of particles removes them from the atmosphere in a matter of weeks or a few months, according to best opinions. On the next placard (6), we see some of the removal processes. Impact on vertical surfaces, such as trees or forests, on grasses of wheatfields, on sides of houses, side of hills, and so forth, removes particles from the troposphere. Further, and by far the most important removal mechanism, appears to be scavening by falling precipitation shown on the right-hand side of the drawing.

THE UNIFORMITY OF FALLOUT

With these introductory meteorological remarks out of the way, let us now return to our question of uniformity of fallout over the globe by particles which are part of the stratospheric or delayed fallout.

The next placard (7) shows on the left hand side the individual soil sample strontium 90—that is the ordinate shows the amount of fallout—fallout values plotted against latitude from pole to pole, as of 1956. That is, we have a sample from one place with a certain latitude, having a given value, and it appears at the point on the graph which you see in front of you. The scatter of points is great, but the general sense of the points is given by the solid black line which is intended to represent a rough average latitudinal profile of strontium 90 fallout.

Mr. Eisenbud tomorrow will describe the limitations and uncertainties as well as the details of the soil sample results. The spread of points around the line reflects the peculiarities of atmospheric removal, that is areas of unusual rain or lack thereof, and idiosyncrasies of soil sampling and analyses which will be described later, by Mr. Eisenbud. One should view the picture broadly, since the uncertainty in individual values may be large.

While this picture fits the meteorological description which I have just offered, namely greater fallout in the north temperature latitudes or between about 25° and 60° N., it would also fit a picture based on the assumption that the greater amount of fallout in the temperate latitudes of the Northern Hemisphere comes from our small Nevada and the small Russian tests. The peak coincides almost exactly with the latitudes of these tests. However, the evidence suggests that the bump is the result of preferred fallout from stratospheric sources as well as from the small Nevada and Russian tests.

Senator BRICKER. One question at that point, Doctor.

Dr. MACHTA. Yes, sir.

Senator BRICKER. I noticed in the public press it is generally believed that the recent rainfall in Washington which brought down some radioactive particles was from the Russian tests. Could you confirm that?

Dr. MACHTA. To the best of our knowledge, the debris remains suspended in the atmosphere for a period of months, and this reported fallout very well could have been the result of the Russian tests.

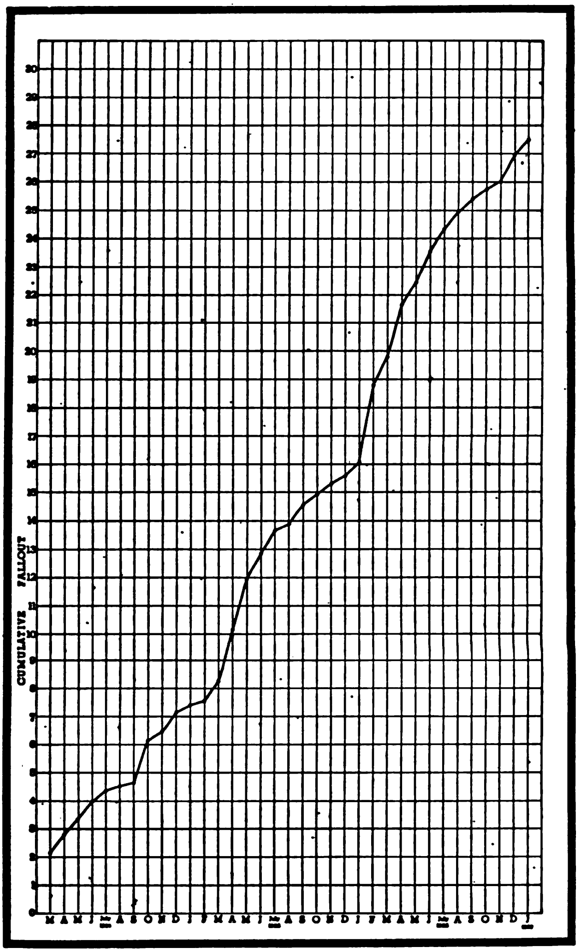
First, although the interpretation is uncertain, the magnitude of the bump calls for more fallout than could have been produced by our Nevada and the smaller Russian tests which have occurred up to the time at which this drawing is applicable. Second, we have a measure of the contribution of tropospheric fallout alone in the United States. In the fall of 1953, strontium 90 fallout was about 5 units compared with 25 or 30 units in the fall of 1956. By 1953, we had conducted 31 of 45 Nevada tests, several Pacific tests series nad the U. S. S. R. had detonated a number of nuclear bombs. The tropospheric fallout since 1953, in my opiinon, could not account for the 20 or 25 additional units of fallout which occurred betwen 1953 and 1956, considering the Nevada and tropospheric Russian fallout.

This graph shows the cumulative amounts of fallout in the vertical plotted against time in months along the horizontal, and shows how in New York City the strontium 90 fallout has been building up with time.

For a third argument, the curve of fallout versus time derived from collections by an exposed pot in New York City is shown in the next placard (8). The changes in slope at various times are evident. It has been suggested that the gentle slope is due to continual drip from the stratosphere and the cliffs due to the additional temporary tropospheric fallout.

Although this thesis is questionable, since the steep rises might be due to more rain at the time, and small tests were held in the U. S. S. R. during the periods of gentle slopes, one can get an idea of the ratio of tropospheric to delayed fallout using this concept. The gentle slope times the period of record yields the stratospheric fallout. The result is that about 50 percent of New York City fallout or 14 units is delayed and 50 percent tropospheric. Finally, in the case of rainwater collections at New York, shown on the same placard (8), it has been possible to analyze for a radioisotope of a short half-life from which a separation of young tropospheric and old stratospheric debris can be made. We find that most of this fallout must be attributed to delayed fallout. Unfortunately, the only radioisotope available,

FIGURE 8



New York City Pot Data

strontium 89, which has only about a 60-day half-life, is not measured as accurately as we would desire.

I have belabored this point because, in the final analysis, the evidence for nonuniform stratospheric deposition should come from fallout data itself and not from meteorological theories. I believe the evidence to be strong enough to indicate nonuniform delayed fallout, so that in future calculations, it should be taken into account. For example, consider the right hand side of the placard (7). The black solid line labeled (1) is a direct copy of the rough latitude profile shown on the left hand side. This is what we see on the ground from all sources in 1956 as best as I can interpret between the points.

The dashed black line (2), below the observed curve, is an estimate, little more than speculation, of the distribution of stratospheric fall-

out up to 1956. The difference between the dashed line and the solid line is what the Nevada tests, the smaller Pacific and the smaller Russian tests have contributed. The lower curve is what has dripped out of the stratosphere. The bump in the north temperate latitude is not as pronounced in the stratospheric fallout curve.

Two cases are now considered. The same amount of fallout has been added to the 1956 observed curve in both cases, an amount of stratospheric fallout about equal to the total already deposited. That is the amount given by the curve on the left, or from all sources. This is not to be construed as indicating that this is necessarily the amount yet to be deposited, but rather it is used for illustrative purposes only. The green curve labeled (3) shows a future profile if the same amount of fallout is added at all latitudes. This is the case of adding everything uniformly to the earth. The red curve (4) with the much more marked peak, shows a profile with pronounced nonuniform future fallout, as I would envisage it. The ratio of the peak value of the nonuniform to the uniform curves is almost 2; the nonuniform peak is about 3 times the world average.

Representative HOLIFIELD. If your theory is right on that, then this would have a direct effect upon the tolerance levels which we are talking about from a worldwide standpoint?

Dr. MACHTA. I am afraid I am not competent to talk about tolerance levels, only about meteorology.

Representative HOLIFIELD. It would more than double, then, the previous estimate as to contamination, would it not?

Dr. MACHTA. May I continue to give my viewpoint on what this actually does in the next paragraph?

Representative HOLIFIELD. All right.

Dr. MACHTA. In my view, these profiles represent the two extremes of distribution of future fallout if the present strontium 90 fallout is doubled. The true distribution should lie between the extremes.

I do not know, in fact, whether the upper curve is correct or the lower curve, but I think there is a possibility the upper one is correct, and we should say the truth lies between the two.

Representative HOLIFIELD. Is this an area where additional research is needed?

Dr. MACHTA. Yes; and I believe the AEC is conducting such research to try to pin this down.

Chairman DURHAM. How about your lower curve on the ground. That is correct, then?

Dr. MACHTA. I did not understand the question.

Chairman DURHAM. Your lower curve, is that accurate?

Dr. MACHTA. No. This is my speculation of what has come out of the stratosphere, too.

Chairman DURHAM. That is speculation too?

Dr. MACHTA. That is correct; and you may see it is estimated as of 1956.

There is one more additional calculation, and this is that nonuniform removal processes also result in nonuniform fallout patterns. Evidence suggests rainfall as being one of the major processes by which the particles are removed from the atmosphere. While agriculture occurs primarily in rainy areas, there are also rainy areas associated with the Icelandic and Aleutian low-pressure systems which

produce enormous amounts of rain over oceans and which are not associated with any agricultural areas. Thus, it appears as though the amount of rainfall in the milksheds and other agricultural areas of the temperate latitudes of the Northern Hemisphere contain very little more rainfall than the average rainfall in the latitude belt in which they exist. However, the rainfall and fallout relationship, is by no means perfect. It is my view, for example, that air masses in which rain has just begun produce more fallout than the air which has not been cleaned by previous rain.

SUMMARY

In summary, I would like to list our knowledge with regard to pertinent meteorology and the uniformity of fallout.

These facts are quite certain, and everyone agrees to them:

1. Much of the long-lived radioactive debris from high-yield tests remains airborne in the stratosphere for years, not weeks or months.
2. Tropspheric fallout lies mainly in the band of latitude of the test and is, therefore, not uniformly spread over the earth.
3. The observed soil data in 1956 reveals nonuniform strontium 90 fallout over the globe. On the average, there is more fallout in the north temperate latitudes.

These points can be presented with varying degrees of confidence:

1. After 2 years, debris in the stratosphere from our Castle test is still not uniformly distributed in the stratosphere. The upper air program of the Atomic Energy Commission can check this thesis in the near future.
2. The stratospheric removal rate and the stratospheric distribution of radioactivity with time depends on the latitude and height of the injection. For example, a contaminant introduced just above the tropopause at 50,000 feet mean sea level at, say, 45° north will come out of the stratosphere much more quickly and in a less dilute form on the ground in the temperate latitude than injections in the Marshall Islands at, say, 80,000 feet. In other words, where and when it will come out depends on where you put it in.
3. Delayed fallout has not been deposited uniformly over the earth. On the average, there is more delayed fallout in the north temperate latitude, even though the main injection was in the Tropics, that is the Marshall Islands.

Finally, we know comparatively little about these points and the conclusions are speculative:

1. The degree of nonuniformity of delayed fallout to date or in the future is unknown. One can put reasonable bounds on the peak value in the temperate latitudes given the amount of delayed fallout.
2. I do not know whether there is also a preferential region of stratospheric fallout in the Temperature Zone of the Southern Hemisphere, but I suspect there might be.
3. The extreme local variability in fallout due to rainfall and other meteorological differences is not known for certain. I would guess that areas as large as milksheds, for example, would not have more than 2 or 3 times the average fallout for the latitude. On the other hand, the lack of rainfall and other removal processes can result in almost zero fallout.

Due to the uncertainty in defining the degree of uniformity, I would recommend that predictions of future fallout be assigned a range of

values based on the 2 extremes just described, in the belief the truth should be between the 2 of them.

Representative HOLIFIELD. Thank you very much, Dr. Machta for that very important presentation. Would you please remain for questions?

Are there any questions at this time of Dr. Machta?

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. VAN ZANDT.

Representative VAN ZANDT. Doctor, describe the jet stream to us. Is it spotty, or is it worldwide?

Dr. MACHTA. By and large the jet stream completely emcompasses the earth. There are areas in which the speeds are greater. However, it is not the jet stream, as such, which is of importance to us, we think. What is important are the places where there are breaks in the tropopause because it is in these areas where horizontal mixing can take materials from the stratosphere and bring them into the troposphere and not have to undergo vertical mixing.

Representative VAN ZANDT. Are they associated with seasons?

Dr. MACHTA. They are usually associated with the jet stream. In the wintertime in the United States, for example, they are located 25° or 30° north. In the summertime, they are much farther north along the United States-Canadian border. The altitude of the jet is about 35,000 feet, give or take a few thousand.

Representative VAN ZANDT. You have had experience with these tests in the Pacific, have you not, Doctor?

Dr. MACHTA. Some experience; yes.

Representative VAN ZANDT. Can you recall at any time immediately after the test when any phenomena developed at high altitudes, as far as weather is concerned?

Dr. MACHTA. In the very local area in which the tests took place, I think there may have been a few showers, which perhaps may not have otherwise occurred. They never extended more than a few tens of miles, I believe, from the area of the tests. I actually was not present at any of the Pacific tests.

Representative VAN ZANDT. On the other hand, other than showers, was there any development of extraordinary winds?

Dr. MACHTA. None to my knowledge, sir.

Representative VAN ZANDT. Some years ago, I think you were the coauthor of a paper that concerned a study made at the request of, I think, this committee regarding the effect of atomic tests on the weather. Would you comment on that paper at this time?

Dr. MACHTA. Well, the research which we have conducted since then does not lead us to believe that our conclusions were in any way erroneous. We still find no connection between the testing of nuclear weapons and the weather. We must admit we are still ignorant on a number of features, and there always exists a remote possibility that something we are not aware of does produce weather. We know of none such.

Representative VAN ZANDT. Doctor, if my memory serves me correctly, you said at that time, that, based on data available, we are simply passing through another cycle as far as world weather is concerned. Do you still hold this view?

Dr. MACHTA. I think the fact we have gone from a drought in the Texas area to what you now observe is sort of evidence there are cycles in the atmosphere.

Representative PRICE. Mr. Chairman?

Representative HOLIFIELD. Mr. Price?

Representative PRICE. Dr. Machta, you made a very interesting negative statement in here. I wonder if you would state it more positively. If you do, it seems to me it would be one of the most salient points of your statement, one of the most interesting points.

On page 10, under speculation No. 3, you say:

> I would guess that areas as large as milksheds, for example, would not have more than 2 or 3 times the average fallout for the latitude.

Stating that positively, you would say they have about 2 or 3 times as much?

Dr. MACHTA. I do not feel the data which are available would allow one to be positive that there are areas in which the fallout is necessarily 2 or 3 times as great.

In the United Kingdom, for example, the fallout readings in 1955 varied, I believe, from about 3.3 up to 10, and they found a very definite, positive correlation with rainfall. The value of 3.3 occurred in a dry area, and the value of 10 occurred in a rainy area. However, what the average should have been for the overall area is not certain.

Representative PRICE. Of course, these milkshed areas you are talking about are the areas where you pick up the most calcium, and where strontium 90 will do the most harm to the human race.

Dr. MACHTA. Yes. I do not think I used the word "milkshed" to indicate the rainfall is unusual in milksheds. I just wanted to indicate areas of that magnitude and size as having on the average not more than 2 or 3 times the total amount of rainfall for the general latitude band. I do not believe I can be any more specific than to indicate an upper bound.

Representative HOLIFIELD. Will the gentleman yield?

Representative PRICE. Yes.

Representative HOLIFIELD. The point of your testimony there is that, of necessity, a milkshed must be located in an area where there is enough rainfall for the production of hay and other material which the animals eat, and you relate that to the fact that rainfall does bring down stratospheric, at least tropospheric radioactive particles. It is upon that sequence of suppositions that you make the statement there would be more radioactivity in that area rather than in a desert-like area where there is no rainfall?

Dr. MACHTA. The data quite clearly prove that this is so. In Brawley, in the Imperial Valley Desert, the values are running much lower than they are for the rest of the United States.

Representative HOLIFIELD. That comes from scientific readings?

Dr. MACHTA. These really are actual measurements of the soil contents, sir, as reported by Dr. Libby and others.

Representative HOLIFIELD. Mr. Durham.

Chairman DURHAM. Dr. Machta, what you said here this morning not only applies to the United States, but has application worldwide?

Dr. MACHTA. This is entirely so, sir.

Representative HOLIFIELD. Do you have any evidence or information regarding the readings of fallout in Japan?

Dr. MACHTA. I would rather that this question be answered by Mr. Eisenbud tomorrow, since he is aware of the details and of the limitations of the data, sir.

Representative VAN ZANDT. Dr. Machta, at this point, may I inquire as to whether or not the information you gave us this morning, is in any way, shape, or form coordinated with the information that may have been passed on to you by foreign countries?

Dr. MACHTA. I believe that one of the points plotted here is taken from a published report from the United Kingdom. Mr. Eisenbud, again, is in a better position to advise you of the information in foreign countries than I am.

Representative HOLIFIELD. We will go into that in detail with him, then, if you prefer.

Dr. MACHTA. Yes.

Representative HOLIFIELD. Because there are several important questions in that area.

Dr. MACHTA. I think he would be much more competent in answering these.

Representative HOLIFIELD. Are there any further questions?

Senator BRICKER. Mr. Chairman?

Representative HOLIFIELD. Mr. Bricker.

Senator BRICKER. Doctor, there are scientists who disagree with you about the intermingling in the atmosphere and the uniformity of fallout over the world ultimately, are there not?

Dr. MACHTA. I am not aware of any that disagree. I may point out that we had a meeting a number of weeks ago with the Meteorology Panel of the National Academy of Sciences Committee on the Biological Effects of Atomic Radiation, at which we discussed this, and I believe that the tenor of conclusions raised by that committee is what I have presented in my paper. I am not aware of other meteorologists who would take exception to my statement.

Representative PRICE. Mr. Chairman?

Representative HOLIFIELD. Mr. Price.

Representative PRICE. Dr. Machta, how did you make this study?

Dr. MACHTA. You mean what led me to the conclusions indicated here?

Representative PRICE. Not only to the conclusions, what is your actual operation, the method of sampling?

Dr. MACHTA. Of sampling the earth?

Representative PRICE. Yes.

Dr. MACHTA. I believe again this is what Mr. Eisenbud will discuss tomorrow. He can verify and talk of the validity of the data. I am sorry. I have simply been given the information, and I am interpreting it in terms of meteorology.

Representative HOLIFIELD. In general, you can say it is from sampling of the soil in different areas of the earth's surface?

Dr. MACHTA. Yes.

Representative HOLIFIELD. And from atmospheric samples?

Dr. MACHTA. Yes, sir. This is in general what it is. The details can be presented later.

Senator PASTORE. Would you say the same as to your conclusion or speculation as to the gathering of this cloud in the Northern Hemisphere, that is, even from the shots that were at Marshall Islands?

Or do you know it is there up in the stratosphere, this deep concentration you talked about?

Dr. MACHTA. In the stratosphere?

Senator PASTORE. Yes. I mean, in your statement here, you rely a great deal on Dr. Brewer of England.

Dr. MACHTA. Yes.

Senator PASTORE. To what extent do you rely on him? What do you know of your own knowledge scientifically as to the existence of this contaminated material in the stratosphere in concentrated form in the Northern Hemisphere, even though the injection was in the tropical part of the earth?

Dr. MACHTA. The answer to this question, sir, is that I do have information which I have not presented to the committee, which is classified, and which leads me to believe it very strongly.

Senator PASTORE. I do not want to get into classification now. I want to get how much of this is speculation, and how much of it is facts.

Dr. MACHTA. The hypothesis of Dr. Brewer is speculation, sir. However, I do have other classified information which leads me to believe that the picture which he has drawn is in fact the truth.

Senator PASTORE. You mean predicated upon the fact that you know it is there?

Dr. MACHTA. Yes, sir.

Senator PASTORE. Then, insofar as Dr. Brewer is concerned, you are merely speculating as to what brings it there?

Dr. MACHTA. Correct, sir. He was offered the mechanism which accounts for the facts at my disposal. I try to proceed as a meteorologist would, sir.

Representative HOLIFIELD. As a layman, let me ask you this question: Is it not possible that we can obtain radioactive particulate from the stratosphere to sample?

Dr. MACHTA. This is already being done by the Atomic Energy Commission, sir.

Representative HOLIFIELD. So we are not speculating on what there is in the stratosphere. We know what there is in the stratosphere, as far as our samples indicate?

Dr. MACHTA. No, sir; I do not think the answer can be given that way. The AEC upper air program as yet does not have results which can clearly prove or disprove the hypothesis I have presented. It will have this information in the very near future.

Senator PASTORE. We have Dr. Brewer's thesis or theory that there is an element or a phenomenon that even though this injection was in the tropical part of the earth, it has directed itself toward the polar regions.

Dr. MACHTA. Correct, sir.

Senator PASTORE. Now, in order to develop that theory, you have to know what is up there?

Dr. MACHTA. Correct, sir.

Senator PASTORE. Otherwise, the theory means nothing?

Dr. MACHTA. Yes.

Senator PASTORE. Therefore, you do know it is there?

Dr. MACHTA. From other information that is classified. It is not the information I was just describing to Mr. Holifield. That will be unclassified.

Senator PASTORE. We know it is there.

Dr. MACHTA. Reasonably well. I will not say positively, but information available to me and to others—incidentally not myself alone—would suggest that is where it is located.

Senator PASTORE. If we did not know it was there, Dr. Brewer's theory would not amount to anything?

Dr. MACHTA. That might be so, sir.

Senator PASTORE. Well, it is so, sir.

Dr. MACHTA. Well, there are other possibilities. For example, it conceivably could have——

Senator PASTORE. Otherwise you would have a hypothesis upon a hypothesis that leads to nothing.

(Conference between Senator Pastore and Representative Holifield.)

Senator PASTORE. Well, all right.

Representative HOLIFIELD. We understand, sir, that you are under certain prohibitions in making testimony in public session, and I am sure this matter can be resolved in executive session.

Dr. MACHTA. Surely.

Representative PRICE. Mr. Chairman?

Representative HOLIFIELD. Mr. Price.

Representative PRICE. In reading a recent speech delivered by one of the Atomic Energy Commissioners on variations of strontium 90, he said:

> For air-fired megaton weapons our present indication is that the fallout is almost worldwide; and for reasons of simplicity, and in the absence of better information at the present time, we work on the model that this is a uniform distribution over the entire world of the material that falls from the stratosphere.

The way I read your statement, you do not quite agree with that.

Dr. MACHTA. In my view, sir, the information which is just now available, and which has been presented here, and which probably has been developed subsequent to the statement you have made, suggests otherwise.

Representative PRICE. This is a very recent speech. This speech was delivered in the latter part of April of this year.

Dr. MACHTA. The data were given to me only about last week or so, sir. This is the data in which the particular model I formulate has been put together, sir.

Representative PRICE. This was delivered before the spring meeting of the American Physical Society by Dr. Libby. It is at variance with the statement you made here this morning.

Dr. MACHTA. I believe the entire Sunshine program—"Sunshine" referring to the stratospheric or lifelong hazard from radioactive debris—is one which is in continual development, and this is not the only area in which modifications of the model and theories have been worked out as new data are obtained.

Representative HOLIFIELD. Are there further questions?

If not, we will excuse you, and thank you very much, Dr. Machta, for a very challenging presentation.

Your article on World Wide Travel of Atomic Energy Debris will be inserted at this point.

[Reprinted from Science, September 14, 1956, vol. 124]

WORLD-WIDE TRAVEL OF ATOMIC DEBRIS

L. Machta, R. J. List, L. F. F. Hubert[1]

For centuries meteorologists have thought of exploring large-scale atmospheric circulations by means of tracers. The literature describes how man has successfully tracked fluorescent particles to a distance of 100 miles,[2] used radioactive tracers across the United States,[3] and followed volcanic ash and forest fire smoke over distances of the order of 1000 miles.[4] Only the dust from a major volcanic eruption, such as Krakatao, has been tracked on a truly global scale.

During two of the nuclear test periods in the Pacific Proving Grounds of the U. S. Atomic Energy Commission, sufficient radioactive debris was thrown into the atmosphere to be deposited in both hemispheres. Measurements of the deposited radioactivity were obtained from exposed sheets of gummed film. The details of the network and the sampling and measurement techniques have been described by Eisenbud and Harley.[5] It should be noted, however, that the deposition of particles on the adhesive surface depends either on the presence of precipitation or, in dry weather, on turbulence to assist the impaction of the particles on the horizontal surface of the paper. It is thus possible to have a cloud of radioactive particles pass two stations simultaneously and have only the station with rain note the presence of the particles overhead. The gummed-film method of collection is recognized as being as crude as it is simple.

The nuclear explosions are treated in this article, the Mike shot on 1 November 1952 and the Bravo shot on 1 March 1954. The shots were similar in that both are described as having had energy in the megaton range, both were detonated at or near the earth's surface on a coral island, and both had atomic clouds that penetrated into the stratosphere. To the meteorologist, the main difference of interest between the two events is the season.

WINDS

The winds acting on the two atomic clouds at the time of detonation are illustrated in Fig. 1. The wind structure has been estimated, when necessary, from observations at nearby locations and times. On both days the tropopause was found at an altitude of about 55,000 feet, and it separated winds blowing from different directions. The easterly winds above the tropopause increased in speed to the highest altitude of the available wind information for the Bravo shot, while for Mike the easterly winds decreased in speed and ultimately changed to westerly winds. The easterly winds in the trade-wind layer, the moist maritime air mass lying near the sea, extended up to about 20,000 feet during the detonation of the Mike device, while for the Bravo shot they were below 10,000 feet. Between the trade-wind layer and the tropopause, one normally finds westerly winds. During the Mike shot these westerlies were temporarily interrupted and became southerly winds, while for the Bravo shot they were toward a more normal bearing.

In Fig. 2 is found the approximate area covered during the early days by that part of the nuclear cloud from the Mike shot which was located below the tropopause. The shaded areas in Fig. 2 have been deduced from meteorological considerations alone, and, in many cases, are subject to considerable uncertainty. Shading was discontinued when the meteorological data no longer warranted any reasonable estimate of the path. The light winds and sparsity of upper-wind observations have made tracing the upper tropospheric portion of the Mike cloud

particularly uncertain. For this reason, the time of passage across the North American mainland is unknown. Tracing was discontinued on 7 November. The tradewind portion of the nuclear cloud appears to have split south of Japan, the upper portion (near 20,000 feet) curving around a Pacific high cell and entering the United States about 9 November.

The estimated meteorological path of the Bravo cloud is shown in Fig. 3. The upper tropospheric portion of the nuclear cloud was traced to the Central American area by about 5 March, and an offshoot extending northward into the United States at about 20,000 feet was detected approximately 1 week later.

Differences between the paths of the Mike and Bravo clouds are evident from Figs. 2 and 3. In part, the differences are seasonal and in part due to the specific meteorology for the shot days. Thus, in November the mid-tropospheric westerly winds are not as strong as they are in March, and they are located farther north, on the average. Further, in November one finds an anticyclonic circulation not far from the Marshall Islands which is not typically present in March. The shallowness of the trade-wind layer during the Bravo shot is an example of a feature unusual for the region during any season.

There has been no attempt to track the stratospheric portions of the atomic cloud because of the sparsity of wind observations at these altitudes. Evidence from numerous isolated high-level winds, not necessarily obtained during the periods of the two nuclear tests, suggests a path that would travel around the earth at about the same latitude as the point of origin. It is interesting to note that in no case was it imperative to rely on stratospheric transport of the nuclear debris to account for the earliest arrival at any point, for the transport of the nuclear cloud in the troposphere appeared to account for the first observations of radioactivity.

An attempt to determine the earliest arrival time at the ground at each point of observation has been undertaken. The results, which are shown in Figs. 2 and 3 as the number of days after the shot day, should in many cases be viewed with caution. First, in many of the stations in the Southern Hemisphere, the deposited activity was so low that it made the arrival date almost meaningless. Second, despite elaborate precautions, it is likely that some gummed films were contaminated during handling. Finally, as noted in the second paragraph the apparent arrival time of the cloud at many stations coincided with rainfall, suggesting that the nuclear cloud may have been overhead some time earlier but that precipitation was required to bring its activity to earth.

FALLOUT

It is noted that, in accordance with the meteorological estimates, the fallout over the United States progressed roughly from west to east during the Mike shot. Fallout from the Bravo event did not appear at the West Coast stations in the United States until 2 weeks after one of the cloud protuberances entered the central United States. Of perhaps greatest interest, although also of greatest doubt, are the comparatively early arrival times in the Southern Hemisphere. Thus, for example, a literal interpretation of the chart reveals that every station in the Southern Hemisphere showed an earlier arrival time than did the United States West Coast stations for the Bravo case. Also of interest are the comparatively late arrival times for the mid-Pacific stations west of the Hawaiian Islands during the Mike fallout. These stations were south of one branch of the nuclear cloud and north of the other.

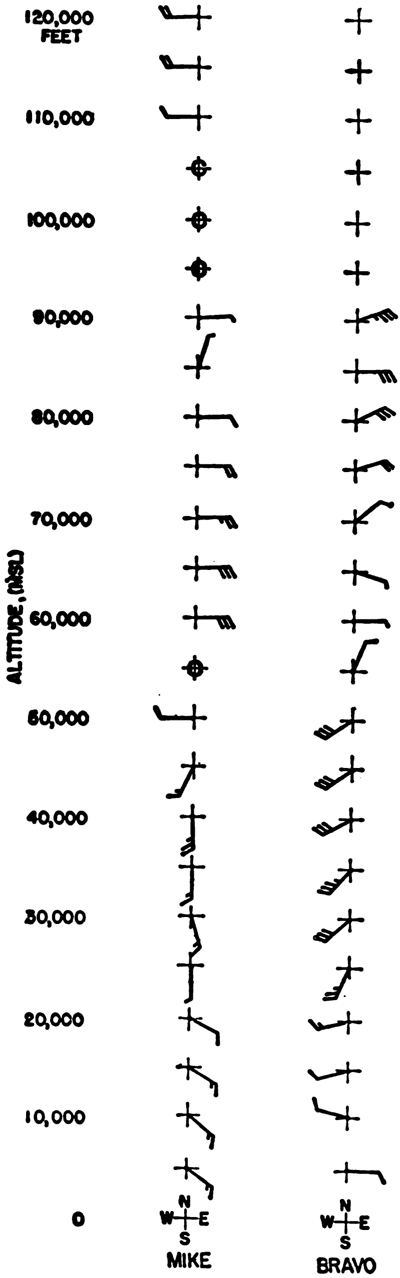

FIGURE 1.—Upper winds at shot time. Arrows blow with the winds, and barbs indicate wind speed; full barb, 10 knots; one-half barb, 5 knots.

The actual fallout at each station and an analysis of the data are shown on Figs. 4 and 5. The units are cumulative decayed beta activity for the first 35 days following each event and are approximately equivalent to millicuries per 100 square miles (the values have not been corrected for the efficiency of the gummed film.) Several features that differentiate the two maps should be noted. First, an average value for all United States and Canadian stations was obtained for the Mike shot, as opposed to values for individual stations during the Bravo shot. Second, the isolines located between points on the West Coast of the United States and points in the Western Pacific Ocean are also based on fallout observations obtained from transport vessels for Bravo. Finally, as is evident, the network was expanded between the two events, primarily in an attempt to locate stations in rainy areas. In many cases, when the period of record is incomplete or the data are suspect, parentheses have been placed around the number. No attempt has been made to reconstruct the isolines for the fallout that occurred within the first 24 hours of the shot.

The comparatively small values obtained at the Southern Hemisphere stations especially during the Mike shot, are immediately evident from the fallout maps. The northern part of the Northern Hemisphere, however, received equally small depositions. The distribution of fallout for the Pacific stations appears to be consistent with the features of the meteorology described, although the branching of the cloud south of Japan in the Mike pattern is based only on scanty observational evidence.

It is apparent that radioactive debris produced by nuclear explosions does not possess all the desired attributes of a tracer for studying global circulations. Information concerning the magnitude and distribution of the radioactivity that remains airborne after the initial fallout is not available. The debris, being particulate, is washed out of the atmosphere and cannot be strictly treated as a conservative property. Thus, for example, the depositions in the Southern Hemisphere may have been low because most of the debris was rained out as it passed southward through the Intertropical Convergence Zone. In addition, the most effective sampling program for the debris provides only the crudest measure of the fallout. Yet, despite these limitations, it appears that the meteorologist can obtain useful information by operating such a network of gummed films during nuclear test periods. Although it is not proposed that special nuclear tests be undertaken for meteorological purposes, it seems reasonable to expect even greater value from future tests using an expanded network and having detonations at other locations and times.

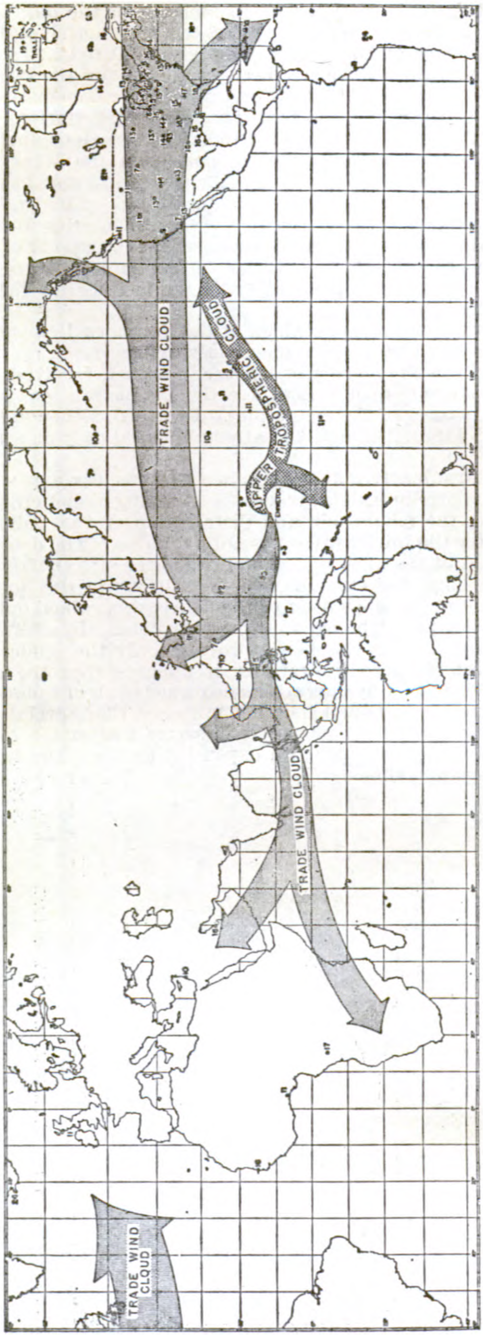

FIGURE 2.—Early history of the Mike cloud. The figures indicate the number of days between detonation and the first ground observation of fission products.

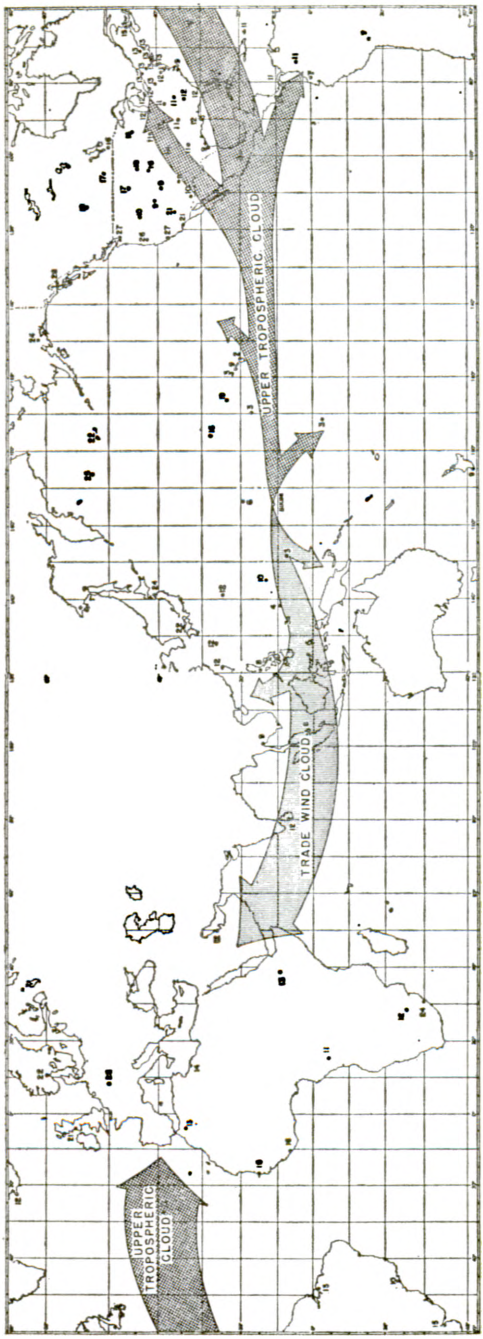

FIGURE 3.—Early history of the Bravo cloud. The figures indicate the number of days between detonation and the first ground observation of fission products.

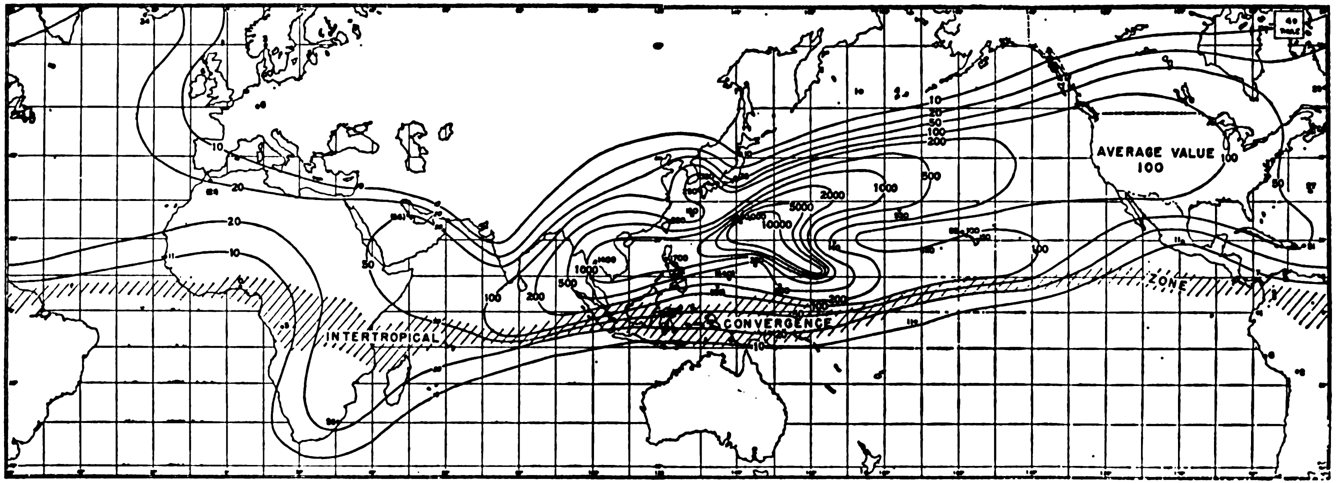

FIGURE 4.—Total radioactive fallout from the Mike cloud in the period from 2 to 35 days after detonation, in millicuries per 100 square miles. Hatching indicates the approximate November position of the Intertropical Convergence Zone, the belt of low pressure that tends to separate Northern and Southern Hemisphere air near the surface of the earth.

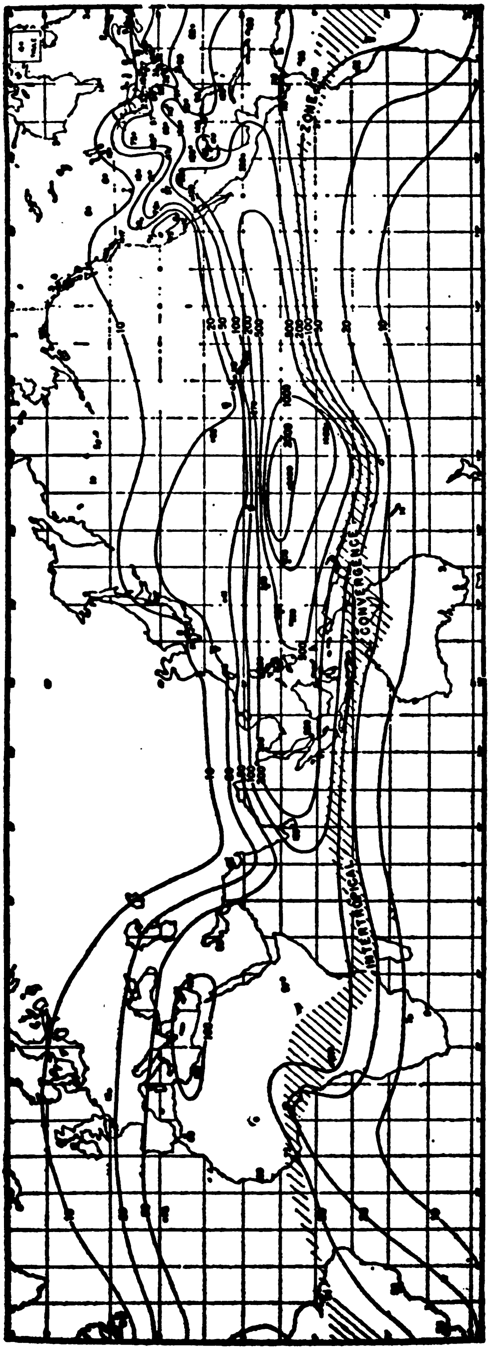

FIGURE 5.—Total radioactive fallout from the Bravo cloud in the period from 2 to 35 days after detonation, in millicuries per 100 square miles. Hatching indicates approximate March position of the Intertropical Convergence Zone, the belt of low pressure that tends to separate Northern and Southern Hemisphere air near the surface of the earth.

93299°—57—pt. 1——12

Our next witness is Dr. Gordon Dunning from the Division of Biology and Medicine of the Atomic Energy Commission.

Dr. Dunning will testify on the topic of Local Fallout: The Mechanisms by Which It Can Affect Man and the Measures He Can Take to Minimize Exposure.

Dr. Dunning, we note that you have a distinguished biography, and your biography will also be inserted with your remarks.

The committee will be in order. The acoustics in this room are very bad, and we will ask our guests to be as quiet as possible so all can hear. We will ask the witness to speak up a little bit louder than usual in his testimony so that all the people can hear.

STATEMENT OF DR. GORDON M. DUNNING, DIVISION OF BIOLOGY AND MEDICINE, ATOMIC ENERGY COMMISSION [3]

Dr. DUNNING. Mr. Chairman, since there is so much relevant material on this subject, if it pleases the committee, I would like to submit the rather voluminous written report for the committee.

Representative HOLIFIELD. Without objection, this report and a letter from David T. Shaw, Assistant General Manager of the AEC will be received for printing in the record, and you may give such summary as you feel necessary.

(The documents referred to follow:)

RADIATIONS FROM FALLOUT AND THEIR EFFECTS

Gordon M. Dunning, Division of Biology and Medicine, United States Atomic Energy Commission, Washington, D. C.

FORMATION OF RADIOACTIVE PARTICLES

At the time of detonation of a nuclear weapon, about 60 different isotopes are formed, representing some 35 elements. Most of these give rise to decay chains consisting of several isotopes so that there may be 170 isotopes produced eventually.

In terms of activity, a 1-megaton detonation (1 million tons) TNT equivalent energy produced by fission of atoms will result in about 300,000 megacuries of radioactivity. measured 1 hour after the burst. In addition there may be present induced radioactive isotopes resulting from the reaction of neutrons released at the time of detonation, with natural materials such as soil and water. (A fusion reaction produces no radioactive substances directly but may cause induced activity because of its release of neutrons.) The total radioactivity of the products of a fission reaction will greatly exceed that of the activity induced in the soil or water. In the case where the fireball clears the ground, there will be a relatively small percentage of the total fission product activity deposited around ground zero and the neutron-induced activity probably will be much greater. However, none of the neutron-induced isotopes that might be produced in appreciable quantities have long half-lives.

Shortly after a nuclear burst, some of the radioisotopes combine with oxygen to form negative radicals while the halogens form halides which combine with the strongly electropositive elements to form compounds. The noble gases such as radiokrypton and radioxeon remain in the atomic state until they decay to a

B&M, 1951–53; AEC, Biophysicist, Division of Biology and Medicine, 1953–55; AEC, Radiation Effects Specialist, Division of Biology and Medicine, 1955—. (Submitted by the Atomic Energy Commission.)

daughter isotope which can form an oxide or halide. With the rapid cooling of the fireball, there is condensation of the isotopes and inert materials.

In the case of an air burst there will be available only small quantities of relatively fine particles of dust in the air and debris from the bomb casing to act as a transport vehicle for the radioisotopes. When the fireball intersects the ground the intense heat melts or vaporizes large quantities of soil and transports them aloft to act as carriers for the condensing radioisotopes. A characteristic toroidal motion sweeps this debris in and around the fireball where the melting temperature is reached and the particles come in contact with the fission products still in gaseous form. Subsequent cooling results in the radioactive isotopes becoming associated within and on the surface of the particles. It has been estimated that from 50 to 90 percent of these particles are between 50 and 1,000 microns in diameter. Of these, probably less than half of the larger particles falling out near the site of the detonation will possess any activity, since most particles will not reach sufficiently high temperatures to incorporate the radioactive materials, and dry, relatively cool, soil is a poor scavenger.

The high yield weapon detonated at the Pacific proving ground in the fall of 1952 resulted in a crater in the coral nearly a mile in diameter and 175 feet deep. Although a minor factor in the crater production might have been the compression of the coral by the blast, probably more than a hundred million tons of material were dislodged and thrown into the air. The exact results might not be reproduced for a detonation over continental land areas or built-up cities but in general the effects would be similar.

DISTRIBUTION OF RADIOACTIVE PARTICLES

For nominal bombs (in the range of 20-kiloton yield) the atomic cloud will not rise above the tropopause. (The tropopause marks the level below which is the turbulent airflow of the troposphere and above which is the relatively stable nonturbulent air of the stratosphere). The cloud from a high yield weapon will penetrate into the stratosphere as illustrated by the photograph on page 196 of the detonation during Operation Ivy in the fall of 1952. Two minutes after the explosion the cloud had risen to 40,000 feet and 10 minutes later neared its maximum height of over 100,000 feet. The smaller particles carried into the stratosphere will settle only very slowly until they reach the troposphere where the turbulent air and rainfall will carry them much more rapidly to the earth's surface.

The stratospheric storage is uniquely significant since the mixture of radioisotopes present there is enriched in strontium 90, the element of most concern for long-term hazards. This is because strontium 90 has a gaseous precursor krypton 90 with a half life of 25 seconds. Thus, at the time when conditions are optimum in the fireball for the oxides and halides to become associated with molten inert particles, only a fraction of strontium 90 has formed and the gaseous krypton parent is largely carried into the stratosphere. This results in the nearby fallout (within several hundred miles downwind) being partially depleted in strontium 90 while at more distant areas will be enriched.

The activity placed in the stratosphere circles and recircles the earth, first at the same general latitude as the burst and then slowly spreading laterally. At the same time there will be a slow diffusion into the tropopause. Initially, there will be more deposition in the same hemisphere (northern or southern) in which the burst occurred but after many months the rate of deposition may become more generally uniform over the entire earth's surface. In terms of strontium 90 about 10 to 20 percent of the activity remaining in the stratosphere may descend each year.

The distribution of the nearby fallout (up to several hundred miles downwind) from high yield weapons detonated near the earth's surface will be determined principally by particle size, initial position in the stem and cloud, and by the wind structure at various altitudes. The particle sizes and the distribution of these particles within the stem and cloud are principally functions of the yield of the bomb, the nature of the surface over which the burst occurs and the quantity of material vaporized. There are uncertainties in our knowledge but figure 1 presents one generalized concept of such an initial distribution. Although the cloud may be 100 miles in diameter the activity probably is not uniformly distributed, but rather is more concentrated near the central and lower portions of the cloud.

The influence of the wind structure at various altitudes on the ground distribution of the nearby fallout is qualitatively represented in figure 2. The last sketch

in figure 2 illustrates the effects of the "shearing" action of the winds when they travel in different directions and/or speeds at the various altitudes through which the particles must fall. Due to these wind conditions, it is possible to obtain fallout patterns ranging from one looking like an ink blot around ground zero at one extreme, to other situations where the fallout material is spread in a long thin finger. In general, the pattern may be expected to approximate an ellipse.

It is clear that such variables as wind conditions and the yields of nuclear bombs and their positions of detonation above different types of surface make it possible to predict fallout patterns precisely. In the case of nuclear weapons testing these variables are either known or can be predicted with good accuracy. However, in civil defense planning, certain assumptions concerning these variables must be used in estimating not only a single fallout pattern, but also possible overlapping patterns in the event of multiple detonations.

RADIATIONS AND FALLOUT

In describing and evaluating the effects of fallout patterns, it is necessary to consider the characteristics of the radiations emitted from the radioactive material. These are of three types: Gamma rays, beta particles, and alpha particles. Gamma rays are the emissions of principal concern, because of their greater penetrating power. The most energetic beta particles travel only a few yards in air and are of concern only when the fallout materials remain in contact with or in very close proximity to the skin, or when tne emitting materials find their way into the body. The amount of alpha-emitting isotopes associated with fallout material is considered to be of relatively minor consequence.

EXTERNAL GAMMA EXPOSURE

The gamma radiation dose that one may actually receive and the biological effects are dependent upon a number of factors, as follows:

1. Radiological decay

The decrease in radioactivity of fallout material roughly follows the relationship of $(\text{time})^{-1.2}$. This means that, for every sevenfold lapse of time after a nuclear explosion, there will be a tenfold reduction in dose rate. For example, if fallout occurs 1 hour after a detonation, such as might occur for 20 or 30 miles around ground zero of a high-yield weapon, the dose rate will be one-tenth of its initial value by the seventh hour. An additional tenfold reduction would require 7 times 7 hours or approximately 2 additional days of waiting. The theoretical[1] dose accumulated from the first to seventh hour after detonation would be approximately the same as that from the seventh hour until 1 week later. Further, this first-week dose would be about twice as great as the entire remaining dose possible for the lifetime of the activity (fig. 3). This rapid decay suggests the benefits of protection in the early periods after fallout and, where possible, delay of entry into a contaminated area.

In localities downwind where initial fallouts might not occur until, say, 24 hours after a detonation, the situation would be somewhat different, in that the radioactive decay would be slower. For example, consider the cases where fallout occurred at (*a*) 1 hour, and (*b*) 24 hours, after a detonation. One day after fallout the dose rate in the first case would be one-forty-fifth of its initial activity (1st hour), but in the second case the dose rate would have decreased to only slightly less than one-half of its initial activity (24th hour).

The above estimates are based on an assumed radiological decay of $(\text{time})^{-1.2}$. This is reasonably accurate for early periods of time after detonation, but the decay may start to vary significantly from the theoretical curve after several months have elapsed (fig. 4). At times later than shown in figure 4 the decay curve would be expected to flatten out due to the presence of long-lived cesium 137 (27-year half life).

2. Weathering and shielding effects

The magnitude and time of occurrence of weathering and shielding makes it impossible to establish a single establishment of a precise rule of effects covering all situations, impossible, yet, these factors are operative in determining the total exposure received from fallout.

---

[1] Calculations of theoretical doses are based on (*a*) the radioactivity decreasing according to $(\text{time})^{-1.2}$, (*b*) there is no loss of activity by weathering effects, and (*c*) the person is out of doors for the time considered.

One example of weathering effects was after the March 1, 1954, fallout on the Marshall Islands in the Pacific. Figure 4 shows the gamma dose rates on the island of Rongelap over a period of about 2 years. In the first 10 days when the winds were light and there was no rainfall, the decrease in activity was roughly consistent with known radiological decay rate. The break between the 10th and 25th day undoubtedly represents the effects of rain which was known to have occurred in that period. Figure 4 suggests, however, that any further reduction in contamination by rainfall was slight.

An example of the effects of winds, occurred after one of the nuclear detonations at the Nevada test site in 1953. Strong winds blew almost at right angles across a narrow band fallout field on the 2d and 3d day after the detonation. The gamma dose rates at 3 feet above the ground on the 4th day were less than predicted by the relationship of $(\text{time})^{-1.2}$ by factors ranging from 3 to 6, while the activity of the soil samples collected on the first day and taken into the laboratory did decrease approximately as $(\text{time})^{-1.2}$. This effect of winds would not be expected to be as great for large contaminated areas of nonsandy soils.

Calculations of shielding and attenuation factors for different types of materials and theoretical calculations for various structures are plentiful (references through 11) (table 1), but more information based on actual field experience is needed. Limited data were obtained during Operation Teapot (spring 1955) where film badges were placed inside and outside of buildings for several days. The ratio of out-of-doors to indoors doses ranged from 1.3 to 7 with 1-room frame buildings providing the least attenuation factor and multiroom concrete block buildings the greater values. This program will be expanded during Operation Plumbbob as will the program of estimating personnel exposure by having a large number of people living around the Nevada test site wear film badges during and following the test series.

3. Gamma energy spectra

The relative biological effectiveness of differing energy photons and their varying depth-dose curves has been shown for X-rays (12). Similar results have been obtained for gamma rays as illustrated by one set of experiments (13) using burros where there was a shift of LD 50/30 values (lethal dose to 50 percent of the exposed animals who died in 30 days) from 684 roentgens with cobalt 60 (1.25 Mev mean energy) to 585 roentgens with Zr–95—NB–95 (~0.7 Mev mean energy). The gamma energy spectra from the mixture of isotopes in fallout is quite complex and is further complicated by the presence of scattered radiation, with its lesser energies, mixed with the direct radiation. Figure 5 illustrates the estimated gamma spectra at 3 feet above the ground following the detonation of March 1, 1954, at the Pacific Proving Ground (14).

4. Geometry of the source

The geometry of the source can make a significant difference in depth-dose curves and resultant biological effects. This may be illustrated by one experiment using swine where the LD 50/30 values for external dose decreased from 500 to 350-400 roentgens when the exposure was changed from unilateral to bilateral (the radiation exposure was first on one side only, then from opposite sides of the subject) (12). With a fallout field, the source probably would be more radial, thus a roentgen as measured in air would have more biological effect than one where the source is unilateral such as from the immediate radiations at the instant of a burst (although there is some scattered radiation), or from X-ray machines which have been used frequently with unilateral beams in developing data on biological effects of radiation.

5. Biological repair factor

It has been recognized that, in general, the longer the period over which a given radiation dose is delivered, the less is the resultant biological effect, except for such aspects as the genetic effects and life shortening. In situations of heavy fallout and relatively large potential radiation doses, the biological repair factor may be considered in estimating incapacitating and lethal doses. Since past experiments usually have been designed for other purposes, the data from these do not readily elucidate the rate of repair or the proportions of reparable and irreparable damage resulting from differently timed doses. Varying relationships have been demonstrated, depending upon the species or even the strain of animal, as well as the criteria selected for study, such as skin damage, life shortening, and LD 50 values. Our present knowledge does not permit establishment of a precise overall relationship for timed doses versus biological effects;

yet there are sufficient convincing data to permit an attempt at estimating the effect of this phenomenon.

Blair, Smith, Sacher, Davidson (15, 16, 17, 18, 19) and others have made extensive analyses of existing data on the effects of time-spaced doses for several species of animals. Generally, the recovery rate for larger and longer lived mammals, such as dogs, is significantly less than for mice. One estimate places the half-time recovery for man as long as 4 weeks (the time for one-half of the biological damage to be repaired) (19).

Since the estimated rate of biological recovery for man is relatively slow, this factor would have its greatest influence where a given total radiation dose was delivered over long periods of time. This would be the case where the fall-out occurred at later times after detonation rather than close-in areas where the fallout is essentially complete in about an hour after the burst, and about one-half of the total possible dose is delivered in the first 24 hours.

NEARBY FALLOUT FROM HIGH YIELD WEAPONS

As an exercise during the National Association of Civil Defense Directors meeting in Washington, D. C., on April 15–17, 1957, it was assumed the 4 bombs were dropped simultaneously as follows: 20 megaton on the Union Station Washington, D. C., 5 megaton on the National Airport, 20 megaton on Baltimore, Md., and 10 megaton on the Patuxent River Naval Air Station. The map on page 195 shows that combined fallout from these 4 bombs. The isodose rate lines are in units of roentgens per hour at 1 hour after detonation. By this time essentially all of the fallout would have occurred in these nearby areas.

Recalling that the radioactive decay is rapid for this fallout that occurs early after detonation, it becomes evident that if adequate protective areas are available it would be wiser for people to remain in place, rather than be exposed out of doors during the period of highest activity. Likewise, if a delay in movement is possible there will be more of an opportunity to evaluate the situation, and to then affect an orderly evacuation.

Since each situation will be unique, no rigid criteria will be proposed here for permissible exposures or for mandatory evacuation, since there may be other factors present as potentially hazardous as radiation. Rather, table 2 was developed to illustrate the kind of thinking and planning possible for civil defense. Three levels of exposure to civil defense workers are shown. The lowest of 25 roentgens is much higher than is permitted in peacetime, yet most personnel will retain their full working capacity even with exposures up to 100 roentgens.

Table 2 suggests several points relative to rescue. One of these, is that higher permitted radiation exposures to rescue crews would allow earlier entry into the contaminated area to affect first aid and general rescue work. Also, in the case of relatively little protection to the populace, there would be a saving in radiation exposure to them. On the other hand, people better sheltered, as illustrated in column V, would receive less total expoure if they stayed in the protected areas until the out-of-doors activity had decreased, and at the same time a delay of entry into the contaminated area would result in less radiation exposure to the rescue crews who might then be used again for other missions.

DISTANT FALLOUT PATTERNS FROM HIGH YIELD WEAPONS

The discussion above suggests the wide variability possible in distant fallout patterns from high-yield weapons and the great variation in radiation dose that one may receive due to shielding and weathering effects. Therefore, the following analysis is intended to be only a generalized one to illustrate the parameters and how they may operate in determining the radiation doses.

Consider the case of fallout from a high-yield weapon where people continue to live in an area without any special measures to protect themselves. Assume (*a*) for the first week following the fallout, the measured gamma activity decays according to $(\text{time})^{-1.2}$, for the second week $(\text{time})^{-1.3}$, and for the third week and thereafter $(\text{time})^{-1.4}$, and (*b*) the shielding factor afforded by normal housing will reduce the out-of-doors daily dose by 25 percent, and (*c*) the half-time of repair of biological injury is 4 weeks. Probably all of these assumptions are conservative, i. e., they overestimate the hazard. Based on these assumptions, figure 6 shows the dose rates at time of fallout or entry into an area that might produce an "effective biological dose" (the term given to the radiation exposure according to the above assumptions) of one roentgen (20). This

graph may be extrapolated to other readings. For example, if a fallout begins 5 hours after detonation and the dose rate at that time is 10 r. per hour, about 67 r. (effective biological dose) will be accumulated provided personnel continues to live normally in the contaminated area. This is computed as follows:

$$\frac{10}{0.15}=67$$

It is frankly recognized that in any single curve, such as that shown in figure 6, there are inherent a number of uncertainties. Criteria based on deliberate analyses of the relevant data, however, may be more valid than those determined under the duress of an emergency situation. Such a simplified graph might provide radiological monitors with a quick, even if rough, estimate of the potential hazards and thus assist in making decisions on questions such as evacuation.

Using figure 6, the idealized fallout diagram on page — was constructed to illustrate a possible pattern from a single high-yield surface burst (20).

The two innermost isodose lines shown were selected to suggest regions where (*a*) a significant percentage of personnel might be expected to die (400 r.) and (*b*) a few percent to become ill (100 r.), assuming continued occupancy of these areas with no special protective measures. These percentages would, of course, rise within the encompassed areas. The 50 r. effective biological isodose line has no unique significance, but suggests the magnitude of dose which might call for emergency measures against radiation exposures even in the face of other possible hazards. Table 3 shows the approximate areas encompassed by the three isodose lines. For areas where the fallout occurs a few hours or more following detonation, many days or weeks will be required to accumulate the major portion of effective biological doses, so that spot decisions involving additional hazards might not be necessary.

The question is frequently asked as to the time one must spend within a shelter or remain outside of a contaminated area. The answer depends upon a number of parameters, such as the criteria established for maximum permissible dose, as well as length of stay within the area of contamination . With knowledge of the magniture of the radiation levels present and an assumed rate of decay, $(t)^{-1.2}$, it is possible to plan and execute a short stay, even in a highly contaminated area. Planning for continuous occupancy requires more extensive analysis. The following data may aid in such evaluation.

The fall out map (idealized fallout diagram on page 196) and table 3 suggest the degree of radiation exposure received in continuous occupancy under normal living conditions beginning with the time of initial fallout. For those entering the contaminated zone 4 months after the first fallout, however, and then living there indefinitely, the area encompassed by the 50 r. effective biological isodose line will have shrunk from about 25,000 to 2,500 square miles. At such time (4 months after fallout), an area of about 1,000 square miles within the 50 r. isodose line might have the highest residual contamination, amounting to about 3 times the does rates at the periphery. The 0.3 r. per week, out-of-doors, isodose-rate line might extend to about the same position as the line marked "50" on the map.

As one attempts to extrapolate such data to 1 year after fallout, the analysis becomes still more difficult and uncertain. The data suggest, however, that if return is postponed to 1 year after fallout, the 50 r. effective biological isodose line will have disappeared. On the basis of these conservative estimates, the 1,000 square miles of highest contamination might have an out-of-doors dose rate of about 4 r. per week after 1 year. Similarly, personnel might accumulate a dose of about 100 r. for the first year following their return, and an additional 90 r. over the next 3 years, independent of the biological recovery factor. It is to be expected that this factor would be relatively great for such long periods of time, thus reducing the effective biological dose below 50 r. The 0.3 r. per week, out-of-doors, isodoserate line might encompass an area somewhat larger than the line marked 400 on the map (20).

For such effects as genetic, it is the total dose received that is important, since biological repair does not enter in such calculations. According to the conservative estimates of weathering and shielding used above, possibly several hundred roentgens might be delivered in the areas of heaviest contamination, from the end of the first year after the fallout occurred until the radioactivity had decreased to essentially zero. However, the foregoing analyses are based on passive factors only, not taking into account the actions of persons themselves in reduc-

ing contamination. If, for example, a permanent return into an area were postponed for 1 year after fallout, the radiological situation probably would have been adequately appraised, and decontamination operations initiated. (This subject will be discussed by others.) Moreover, with the return of a populace into a known contaminated area, more than normal precautions might be expected in regard to occupancy of the more protective types of buildings and reduction of time spent out of doors.

Of course, greater degrees of contamination could result from multiple, overlapping, fallout patterns. There is a need for continuing studies of these problems.

ENVIRONMENTAL CONTAMINATION

Radioactive contamination of an area will, of course, influence agricultural pursuits. An evaluation of these problems involves complex and difficult studies which will not be attempted here. In terms of civil defense, however, there is one phase that should be noted here.

The relatively heavy fallout that occurred on some of the Marshall Islands in March 1954 provides the most direct data. Since the time of this fallout there have been 10 radiological and biological surveys of these islands. All of these data are summarized in a report prepared by the Atomic Energy Commission and in press with the Government Printing Office (21).

There are strikingly wide variances in the degree of gross contamination in the soils and in the plant and animal life. Likewise, relatively large ranges in values were found for the individual isotopes in the plants and animals. Any conclusions, therefore, must be of only the most tentative and generalized nature.

The data do suggest that, in terms of strontium 90, the isotope of principal concern, this activity built up in the plantlife over the first year after fallout and then started decreasing slowly. By using very rough approximation, and extrapolations, the data suggest that, if plantlife had been growing in the area of great contamination, i. e., where the gamma dose rates extrapolated to H plus 1 hour would have been 2,500 roentgens per hour, it might have contained 10–30 microcuries of strontium 90 per kilogram of calcium, at 1 year. The corresponding values for the soils are several times higher. If an assumption is made that there is a discriminatory factor of about 4 for the Sr-Ca ratio in plants versus bones, the above data suggest possible levels of strontium 90 in the bones of animals from continuous consumption of this food of a few to several microcuries of strontium 90 per kilogram of calcium. The maximum permissible body burden for adult atomic-energy workers is 1 microcurie of strontium 90 per kilogram of calcium.

There is some confirmatory evidence for this crude evaluation. A variety of native animals were left on the island of Rongelap after the fallout in March 1954. They have been collected and sacrificed serially in time. Even after 2 years of continuous occupancy, it was reported that there were no pathological changes that could be ascribed to radiation (22). Their bones showed from about a one-tenth to a few tenths of a microcurie of strontium 90 per kilogram of calcium. Since the areas of highest contamination were about 12–14 times greater than Rongelap, an extrapolation would suggest values in the same range as above, i. e., a few to several microcuries of strontium 90 per kilogram of calcium if animals had lived in the area of great contamination.

The Pacific island soils have higher calcium content than most soils in the United States, and of course there are differences in the type of plantlife and in the climate. However, theoretical calculations suggest that the same fallout in the United States might result in something like 100 microcuries of strontium 90 per kilogram of calcium in the soils with the highest contamination. With assumed discriminatory factors from soil to bones of 10 or more, the implied eventual body burden of strontium 90 is of the same magnitude in the Pacific.

The uncertainty of these data, however, would not deny the possibility that for a similar fallout in the United States there might eventually result a body burden of 10 or more microcuries per kilogram, if people were to subsist entirely on food from the area of highest contamination. With maintained values 2 to 3 times this amount, it might be expected that a few percent might die of bone tumors after a latent period of 15 to 20 years. It would be expected, however, that the strontium 90 content in the food supply would slowly decrease with time. Any measures taken to reduce the uptake of strontium 90 into the food supply, and any supplemental foods from less contaminated areas would lower the strontium intake.

For civil-defense purposes, a full evaluation of the whole environmental contamination problem is needed, especially for the cases of multiple, overlapping, fallout patterns from many nuclear detonations which might occur under wartime conditions.

EXTERNAL BETA EXPOSURE

The second principal emission from the fallout material is beta particles. These are essentially high-speed electrons, of which even the most energetic travel only a short distance into the skin. (See the next section for discussion on internal exposures.) If large enough radiation doses are delivered by these beta particles, the skin may first show erythema (reddening) and then proceed to more serious damage. If a sizable fraction of the body should suffer serious skin damage from these beta radiations, the results would be similar to those from thermal burns, i. e., serious injury or death.

There is little doubt that "beta burns" can and have occurred. In the case of the Marshallese who were in the fallout from the detonation at the Pacific on March 1, 1954, most of the more heavily exposed showed some degree of skin damage, as well as about half of them showing some degree of epilation due to beta doses (22). However, none of these effects were present except in those areas when the radiation material was in contact with the skin, i. e., the scalp, neck, bend of the elbow, between and topside of the toes. No skin damage was observed where there was a covering of even a single layer of cotton clothing. In fact, the beta radiations emanating from the radioactive material on the ground should have been adequate to produce detectable skin damage (based on the amount of contamination present), yet this was not observed.

These findings indicate the obvious benefits to be expected from (*a*) remaining inside during the time of actual fallout to reduce the possibility of direct body contamination, or, if out of doors, to keep the body covered, and (*b*) early removal of the body contamination, since higher doses are delivered during early times after fallout.

The Marshallese were semiclothed, had moist skin, and most of them were out-of-doors during the time of fallout. Some bathed during the two-day exposure period before evacuation, but others did not, therefore, there were optimal conditions in general for possible beta damage. The group suffering greatest exposure showed 20 percent (13 individuals) with deep lesions; 70 percent (45 individuals) superficial lesions; and 10 percent (6 individuals) no lesions. Likewise, 55 percent (35 individuals) showed some degree of epilation followed by a regrowth of the hair. However, during this same period of time they received a whole-body gamma dose of 175-roentgens—a value approaching lethality for some of those exposed. These data, together with others, indicate that the external gamma radiation would be the controlling factor for making such decisions as to evacuation, although recognizing that any beta exposure would be an additional body insult.

INTERNAL EXPOSURES

The principal factor in evaluating long-term hazards from ingestion and inhalation is the doses delivered to the bones by isotopes of strontium. This subject will be discussed in detail by others.

The principal hazards from intake of relatively large amounts of radioactive fallout for several weeks immediately following a nuclear detonation are doses to the:

(*a*) gastrointestional tract, from the gross fission product activity,
(*b*) thyroid, from isotopes of iodine, and
(*c*) bone, principally from isotopes of strontium and barium-lanthanum.

The solubility of the fallout material is a major factor in determining the resultant fate, and thus radiation doses, within the body. The solubility varies, depending among other factors upon the surface over which the detonation occurred. The fallout material collected in soil samples at the Nevada test site has been quite insoluble, i. e., only a few percent in distilled water and roughly 20 to 30 percent in 0.1 N HCl. However, it would be expected that the activity actually present in drinking water supplies would be principally in soluble form. The water collected from a well and a cistern on the island of Rongelap about 21 months after the March 1, 1954, fallout, was found to have about 80 percent of the activity in the filtrate, but there was an undetermined amount that settled to the bottom. Other data suggest the material to have been about 10 to 20 percent soluble in water.

Figure 7 shows relative doses to the body organs, based on the assumptions that (*a*) 90 percent of the material is insoluble (when calculating doses to the

gastrointestinal tract), (*b*) all of the isotopes of iodine are soluble (when estimating doses to the thyroid), and (*c*) 25 percent of the ingested strontium isotopes and 7 percent of the barium-lanthanum reached the bones. It may be seen that ingestion of a given amount of fission product activity on the fourth and fifth days may result in nearly 2½ times the dose to the thyroid as to the lower large intestine. For a continuous consumption of fallout material from the 1st hour to the 30th day the ratio of doses is about 1.7. Table 4 indicates the amount of ingested fission product activity to produce 1 rad dose to the lower large intestine.

Analyses of past data strongly indicate the quantity of fallout material taken in for times immediately following a detonation: (*a*) by inhalation is very much less than by ingestion (unless of course one does not eat or drink), and (*b*) may come from surface contamination of the food rather than by the soil-plant-animal cycle.

How much intake is actually permitted depends upon many factors including the essentialness of the food and water to sustain life, and one's philosophy of acceptable biological risks and damages in the face of other possible hazards such as mass evacuation. By using table 4 and figure 7, an estimate may be made of the radiation doses that might result from the ingestion of a given amount of fission product activity. In determining how much actual ingestion, and thus the radiation doses that might be permitted, reference may be made to table 5 which suggests the biological effects from certain doses.

Such evaluations as attempted here are necessary and valuable for planning purposes, but once the fallout occurs the emergency of the situation may preclude immediate analysis of the food and water suppiles. Further, the abstinence from food and water because it might be contaminated could not be continued indefinitely. Therefore, the following three commonsense rules are suggested:

1. Reduce the use of contaminated food and water to bare minimum until adequate monitoring can be performed; use first any stored clear water and canned or covered foods; wash and scrub any exposed foods.
2. If the effects of lack of food and water become acute, then use whatever is available but in as limited quantities as possible. Whenever possible select what seems to be the least likely contaminated water and/or foodstuffs.
3. Since it is especially dsirable to restrict the intake of radioactivity in children, give them first preference for food and water having the lowest degree of contamination.

In an area of heavy fallout one matter to consider is the relative hazards from the external gamma exposure versus internal doses from ingestion of the material. One of the best evidences on this point was the fallout that occurred on the Rongelapese in March 1954. Those in the highest exposure group received 175 roentgens whole body external gamma exposure yet their body burdens of internal emitters were relatively low (22). These and other data suggest that:

If the degree of contamination of an area for several weeks immediately following a nuclear detonation is such that the external gamma exposure would permit normal and continuous occupancy, the internal hazard would not deny it.

This is based on such reasonable assumptions of (*a*) about 50 percent reduction of gamma exposure from out-of-doors doses afforded by living a part of each day in normal family dwellings, (*b*) washing and/or scrubbing contaminated foods, and (*c*) excluding areas where relatively little fallout occurred, but into which may be transported highly contaminated food and/or water. After longer periods of time during which the gamma dose rates in an originally highly contaminated area have decreased to acceptable levels, it probably would be necessary to evaluate the residual contamination for the bone seeking radioisotopes, especially strontium 90.

NUCLEAR WEAPONS TESTING

Since 1951, the United States has conducted 11 series of nuclear tests, 5 at the Nevada test site and 6 at the Eniwetok Proving Ground, for a total of more than 63 test detonations. A sixth series is currently underway at the Nevada test site. The fallout on the inhabitants of some of the Marshall Islands in March 1954 (which will be discussed by others) and fallout on some Japanese fishermen, have been the major effects off the testing areas. The only other off-site damage has been in the United States where the blast wave has caused minor structural damage for which about $45,000 has been paid in claims (23), and fallout that occurred on some horses and cattle grazing within 20 miles of ground zero causing skin burns for which about $15,000 was paid.

At the Eniwetok Proving Ground, where the larger devices are tested, the warning area covers nearly 400,000 square miles. This area is under constant sur-

veillance during the time of testing both by surface ships and by aircraft. Starting 2 days prior to a detonation, the search is intensified in the sector of probable fallout. If any transient ship is located in the warning area, it is advised to leave and the detonation is delayed until it is clear.

Fully manned weather and fallout prediction units are an integral part of the task force conducting the tests. Since the larger detonations in the Pacific require additional information on the upper air, new types of high-altitude balloons and missiles are used. Nine weather stations are established by the task force during the test series on islands around the site, in addition to the eight regular weather stations in operation on other islands.

After each detonation, aircraft track the radioactive air out for several hundred miles. Other aircraft, with special monitoring equipment fly over land and sea areas to measure any residual contamination.

Through the cooperation of the United States Public Health Service, trained monitors were present during Operation Redwing (spring 1956 series) on the populated islands of Wotho, Ujelang, and Utirik.

As would be expected, the delineation of fallout patterns in the wide expanses of the Pacific is difficult. For the immediate monitoring, aerial surveys are conducted as mentioned above, automatic equipment are placed on land areas, and a variety of ships, skiffs, and buoys are utilized. Following each test series, large-scale radiological and biological surveys are made. Data from these surveys have been summarized by the Commission in a document soon to be published by the Government Printing Office (21).

The Nevada test site covers an area of about 600 square miles, with the adjacent 4,000 square miles being a United States Air Force gunnery range (24). Surrounding these areas are wide expanses of sparsely populated land. For general safety, as well as security, the Nevada test site is closed to the public. Aerial and surface surveys are made to insure that no persons or animals wander into the area. Each nuclear detonation is publicly announced ahead of time.

As a part of the test organization there is an advisory panel of experts in the fields of biology and medicine, blast, fallout prediction, and meteorology. A series of meetings is held before the firing of each shot to weigh carefully all factors related to the safety of the public.

A complete weather unit is in operation at the Nevada test site, drawing upon all of the extensive data available from the United States Weather Bureau and the Air Weather Service, plus six additional weather stations ringing the test site. These data are evaluated for the current and predicted trends up to 1 hour before shot time. A shot can be canceled at any time up to a few seconds before the scheduled detonation. In the past, more than 80 postponements have been made due to unfavorable weather conditions.

Several measures have been used to reduce the radioactive fallout off the test site. First, of course, only small nuclear devices are tested at Nevada. Since the greater the height of the fireball above the surface the less is the fallout in nearby areas, the test towers have been extended to 500 feet, and during Operation Plumbbob (spring 1957) there will be at least one 700-foot tower. Also, a new technique of using captive balloons is being developed. Extensive tests are being conducted to determine the feasibility of detonating nuclear devices so far underground that all of the radioactive material will remain captured and thus, of course, completely eliminate any fallout.

Prior to each nuclear detonation a warning circle is established for aircraft, designed to provide control of aerial flights within the area of predicted path of the atomic cloud. A representative of the Civil Aeronautics Administration is assigned to the test organization and assists in establishing the controlled area. This may typically extend about 150 miles in radius and be in force for a period from about H minus one-half hour to H plus 10 hours. All aircraft are required to check through the Civil Aeronautics Administration before flying in this area.

After each nuclear burst, aircraft from the test organization track the cloud until it is no longer readily detectable. Behind this come other aircraft to plot the fallout pattern on the ground. This survey is repeated on D plus 1 day.

The off-site monitoring program during Operation Plumbbob (spring 1957) illustrates the extensive system organized not only to take numerous radiological measurements but also to provide close liaison with the citizens of nearby communities. The Atomic Energy Commission and the United States Public Health Service jointly organized a program wherein the areas around the test site are mapped out into 17 zones. A technically qualified man has been assigned to live in each zone. His duties consist not only of normal monitoring activities

but also, prior to and during the test series, of learning the communities and families in his zone, getting to know the people and having them know him. In addition to the 17 zone commanders, as they are called, there are 8 mobile monitoring teams on call to go to any locality to assist if needed or to travel to areas outside the 17 zones.

Four additional monitoring programs are also in operation. One of these projects is primarily of research nature yet provides radiation monitoring data out to 160 miles or more from the test site. A second program is a unique system of telemetering, whereby instruments are placed in about 30 communities around the test site and connected to commercial telephone wires. The operator sits at the control point and, by placing a normal telephone call, receives back signals that are translated in a matter of seconds into gamma radiation dose rates. A third project consists of automatic instruments located in another 15 communities that permanently record the gamma dose rates continuously from the beginning to the end of the test series. A fourth program consists of aerial surveys with special gamma detection instruments.

Extending outward from the test site across the country are 38 United States Public Health Service monitoring stations established in cooperation with the Atomic Energy Commission, and 11 AEC installations (see tables 6 and 7). In addition, through the cooperation of the United States Weather Bureau 93 stations in the United States make gummed paper collections of fallout (table 7). These gummed-paper collections are also made worldwide at 73 other locations by arrangement with the Department of State, United States Weather Bureau, United States Air Force, and Navy (table 9).

RADIATION EXPOSURES TO THE PUBLIC

The data and their evaluation concerning strontium 90 produced by nuclear weapons testing will be discussed by others at this hearing.

The external gamma exposures through September 1955 may be described briefly as follows:

"* * * With respect to the gamma dose, the average value for the United States is higher than it is for the rest of the world. The range of values in the United States is relatively narrow, 6 to 49 millirads, except for Salt Lake City (160), Grand Junction (120), and Albuquerque, N. Mex. (110). The representative dose for eastern United States is about 15 to 20 millirads, with slightly higher values in the Middle West and lower values on the west coast.

"The cumulative gamma dose at the foreign stations is in the range of 4 to 23 millirads, except for some of the Pacific islands, where the range is from 13 to 150 millirads * * *" (25).

These are infinity does, i. e., the maximum possible exposures one might receive if he were out of doors for the lifetime of the radioactivity, there were no weathering effects, and the activity decayed according to $(\text{time})^{-1.2}$. The actual radiation exposures will vary with changes in these conditions, but roughly may approximate one-half of the infinity dose.

In summarizing, the data on radiation exposures from fallout, the National Academy of Sciences-National Research Council report said (26):

"* * * it may be stated that United States residents have, on the average, been receiving from fallout over the past 5 years a dose which, if weapons testing were continued at the same rate, is estimated to produce a total 30-year dose of about *one-tenth of a roentgen;* and since the accuracy involved is probably not better than a factor of 5, one could better say that the 30-year dose from weapons testing if maintained at the past level would probably be larger than 0.02 roentgens and smaller than 0.50 roentgens. * * *

"The rate of fallout over the past years has not been uniform. If weapons testing were, in the future, continued at the largest rate which has so far occurred (in 1953 and 1955) then the 30 year fallout dose would be about twice that stated above. * * *"

Gamma radiation exposures near the Nevada test site are generally higher that the average for the United States. The map on page 195 shows the estimated gamma exposures accumulated from all tests at the Nevada test site. Table 10 lists all of the communities that have received sufficient fallout to result in an estimated 0.2 roentgens or more to the inhabitants. In addition to this list, the highest fallout level noted to date in an inhabited place around the Nevada test site occurred in 1953 at a motor court near Bunkerville, Nev., where about 15 people might have accumulated 7 to 8 roentgens if they had continued to live there indefinitely.

The National Academy of Sciences-National Research Council Report recommended: (26)

"* * * That for the present it be accepted as a uniform national standard that X-ray installations (medical and nonmedical), power installations, disposal of radioactive wastes, experimental installations, testing of weapons, and all other humanly controllable sources of radiations be so restricted that members of our general population shall not receive from such sources an average of more than 10 roentgens, in addition to background, of ionizing radiation as a total accumulated dose to the reproductive cells from conception to age 30. * * *

"* * * That individual persons not receive more than a total accumulated dose to the reproductive cells of 50 roentgens up to age 30 years * * * and not more than 50 roentgens additional up to age 40 * * *."

The National Committee on Radiation Protection and Measurement (27) has recommended that, "The maximum permissible dose to the gonads for the population of the United States as a whole from all sources of radiation, including medical and other manmade sources, and background, shall not exceed 14 million rems per million of population over the period from conception up to age 30, and one-third that amount in each decade thereafter. Averaging should be done for the population group in which cross-breeding may be expected." (27)

Since natural background radiation is roughly 4 roentgens per 30 years, the value for manmade sources becomes about 10 million man-rems for a population of one million. This particular unit was selected because of genetic considerations, that is, radiation doses to relatively large populations. The average exposure to only those communities around the Nevada test site that experienced the greatest amount of fallout (0.2 roentgens or more) is 0.6 roentgens for the 6 years since the regular nuclear tests were started. The round numbers are 58,000 man-roentgens for 100,000 people. If the area considered around the Nevada test site is enlarged to include 1,000,000 people the average exposure is about 0.1 roentgens for the 6 years, or at a rate of about one-half roentgen per 30 years. This is one-twentieth of the recommendation of the National Committee on Radiation Protection and Measurement for maximum exposures.

The highest measured concentration of fission product activity in the air off the Nevada test site was at St. George, Utah, during the spring 1953 test series, amounting to about 1.3 microcuries per cubic meter of air averaged over a 24-hour period. It was estimated that the radiation dose to the lungs from this activity was less than that delivered every month by naturally occurring radioactive isotopes in the air that we breathe.

The highest measured concentration of activity from fallout material in water off the controlled area was at upper Pahranagat Lake, Nev., in the spring of 1955 amounting to 1.4×10^{-4} microcuries per milliliter at 3 days after the detonation. This is one-thirty-sixth of the operational guide—an amount that is considered safe for continuous consumption.

FIGURE 11.—Detonation during Operation Ivy; Fall 1952.

U. S. ATOMIC ENERGY COMMISSION,
Washington, D. C., March 20, 1957.

Hon. CHET HOLIFIELD,
Chairman, Military Operations Subcommittee,
Congress of the United States.

DEAR MR. HOLIFIELD: This is in reply to your letter of February 25, 1957, requesting "(*a*) the roentgen readings on Rongelap Atoll as of January 1, 1957; and (*b*) the roentgen readings as of the same date on the downwind island of Bikini Atoll where the fallout might be expected to simulate that of a suburban area of a big city." We do not have the data in the exact form which you requested, but are glad to give you the following information concerning radiation levels in these areas.

The last survey which we made of Rongelap was at the end of July 1956. This survey showed dose rates ranging from 0.2 to 0.5 milliroentgens per hour with an average of 0.4 milliroentgens per hour. Previous surveys had indicated that the dose rates in July 1956 would be aboout 0.1 milliroentgens per hour. The higher value found in July 1956 was undoubtedly due to the small additional fallout that occurred during Operation Redwing. If so, because of the relatively rapid decay of this fresh radioactive material we would expect that at the present time the radiation level is again in the neighborhood of 0.1 milliroentgen per hour or less. This is about one-half the currently recommended maximum permissible rate of exposure for general populations.

Gamma dose rates on the island of Rongelap observed in previous surveys are shown on the attached graph. The plotted points through which the solid line is drawn represent gamma dose rate readings at a point of 3 feet above the ground. The break in the curve between the 10th and 25th day was undoubtedly due to the first heavy rains that were known to have occurred after the detonation. Aside from this break you will note that the observed decrease of the gamma dose rate during the first 2 years follows rather closely values predicted from theoretical considerations.

The gamma dose rates on other islands in Rongelap Atoll have not been followed as closely but the data indicate similar *rates* of decay with the most heavily contaminated island being about 12 times higher activity than Rongelap Island. This was the uninhabited island of Naen on the northwestern rim of the atoll. The decay rates have not been similarly followed on the islands of Bikini because additional fallout occurred on these islands from subsequent detonations during Operation Castle and again during Operation Redwing. It would be expected, however, if the rates of decay for the March 1, 1954, fallout could have been followed, they would have been somewhat similar to those shown in the graph. (See p. 192.)

For any single fallout event, the degree of initial contamination in any area depends upon many variable factors. In general, the data suggest that after March 1954. Also plans are being developed for a continuing and long-range and the corresponding radiation dose rate in close-in areas (i. e., 10 to 20 miles) are not greatly higher than at 100 miles downwind, under wind conditions of some 15–20 miles per hour. However, it is important to realize that the radiation dose received by unprotected persons in the close-in areas is greater because they would receive a substantial portion of their total dose during the time required for the fallout to reach the more distant areas. You will recall that the fallout on the island of Rongelap started at about 5 hours following the detonation.

The Atomic Energy Commission is currently preparing a report summarizing the data from the surveys that have been made in the Marshall Islands since March 1954. Also plans are being developed for a continuing and long-range program of monitoring these areas.

Sincerely yours,

DAVID L. SHAW,
Assistant General Manager.

Dr. DUNNING. In describing and evaluating the effects of fallout, it is necessary to consider the characteristics of the radiations emitted from the material. These are of three types, as you learned yesterday: Gamma rays, beta particles, and alpha particles.

The gamma rays are the emissions of principal concern, because of their greater range, and we will speak primarily of them.

The gamma radiation dose that one may actually receive from fallout, and the biological effects are dependent upon five principal factors. Let us consider each of these 5 factors briefly, and then attempt to integrate them into 2 illustrative examples.

The first factor is radiological decay.

The decrease in radioactivity of fallout material roughly follows the relationship of time to the −1.2 power.

I have illustrated on the first chart the doses that might be accumulated if fallout were to occur 1 hour after detonation. If you were standing out of doors, fully exposed, from the first to the seventh hour after the detonation, one would accumulate 32 percent of the total possible exposure in that area. From the seventh hour to 1 week later, 32 percent more, and from 1 week to the full lifetime of the radioactive material, the other 36 percent. This is based on a 1-hour fallout. (See p. 191.)

If the fallout occurs at later times, then the exposures accumulate much less rapidly. In other words, it would take much more than the first 6 hours to accumulate the 32 percent of the total possible dose.

The second principal factor that determines doses and effects is weathering and shielding effects.

Obviously, these vary from time to time and place to place, so we cannot make any precise evaluation of them, but we can make some generalizations.

Based on data from the Pacific tests, especially the one of March 1954, we found that the dose rates on the islands were reduced by a factor of about two after the first heavy railfall; but after that the subsequent rainfalls did not seem to reduce these dose rates appreciably. However, there are good data lacking on the effects of rainfall on relatively heavy fallout patterns for large land masses having different soil characteristics, or on built-up areas.

The next chart summarizes some of the estimates of shielding that might be expected from different type structures. These are based principally upon theoretical calculations, since there are a paucity of field data. (See table 1, p. 182.)

In an ordinary 1-story frame house, such as many of us live in, on the first floor there would be about 50 percent as much exposure as there would be out of doors. In the basement, the center, about 10 percent as much as that out of doors; on the side of the basement less than 10 percent; in other words, better protective factors.

For a multistory reinforced concrete, on lower floors away from windows, a factor of 10; and for the basement we are again down to one-tenth of 1 percent of the out-of-doors exposure.

Likewise, with shelter equivalent to 3 feet of earth, we are down to one-tenth of 1 percent of the outdoor exposure.

Senator HICKENLOOPER. Mr. Chairman?

Representative HOLIFIELD. Senator Hickenlooper.

Senator HICKENLOOPER. May I ask about the building, the frame house. Does that contemplate all the windows closed, or does it contemplate free access of air? Or is it in the blast area? Or where are these houses located, for the record?

Dr. DUNNING. The assumption is made here that the windows are closed. If the windows and doors are open, this in itself makes little difference, but then, as you implied this will allow the radioactive material to drift into the house, and, of course, raise your level.

Senator HICKENLOOPER. How does the radioactive material get into the house if it is a closed structure?

Dr. DUNNING. These are the actual gamma rays coming from the material lying outside, and they will pass right through the walls, and in doing so will be partly absorbed, but nevertheless in this case we estimate about half of them will get through the walls.

Senator HICKENLOOPER. Gamma rays coming from particles in the atmosphere?

Dr. DUNNING. That is right, sir.

Representative HOLIFIELD. There is a significant difference on the point that Senator Hickenlooper brought up, and that is that your gamma rays are rays which penetrate building materials in the one instance, but in the case where the windows have been blown out or the doors are open, the fission fragments can drift in and settle and emit the same type of rays without any shielding at all. Is that not true?

Dr. DUNNING. That is correct, sir.

One example of the effect of winds—one example of winds occurred at the detonation at the Nevada test site in 1953, when strong winds blew almost at right angles across a narrow band of fallout field on the second and third day after the detonation. The gamma dose rates on the fourth day were found to be less than predicted without winds by factors ranging from 3 to 6. In other words, the winds simply blew this material away, or it worked itself into the ground. But the effect of winds would not be expected to be as great as this for large contaminated areas of nonsandy soils.

The third factor that affects doses and biological effects is that of energy of these rays, discussed at some length yesterday. So I merely mention that the energy does determine the depth to which these rays will penetrate an object as large as the human body, and also the energy of these rays will determine the amount of energy that is released to the tissues in passing through the body.

It is quite a complicated process to try to estimate these various gamma spectra of the rays and to estimate their biological effects, but this is what is attempted when you say people receive so much dosage.

The fourth factor is that of geometry. That is, it is found if you have radiation coming from only a point and passing through the body from only one direction, as it passes through the dose will drop off within the body. Simply some of the energy is absorbed.

In the case of fallout, however, we have rays coming at you in various directions, sometimes all directions, and so we find then that the dose delivered within the body is almost uniform, that is, you get almost as much in the center of the body as near the surface.

The last factor in determining dose and effect is the biological repair factor. It has been recognized, in general, that the longer the period over which a given radiation dose is delivered, the less is the resultant biological effect, except for such aspects as genetic effects. In situations of heavy fallout and relatively large potential radiation doses, the biological repair factor may be considered in estimating incapacitating and lethal doses.

Representative HOLIFIELD. At that point, will you give us an explanation of what you mean by lethal doses, what type of cells in the body can be repaired, or be replaced, and what type of cells or parts of cells are permanently mutated?

Dr. DUNNING. It is not so much the question of the cells as the effect on the cells. As you intimated in the last part of your statement there, it is believed that genetic effects or mutations, whether it be mutations of the gene cells or the somatic cells, the living cells within the person, these effects are linear with dose. That is, if you double the dose, you double the mutations.

What I spoke of here was more the gross effect. In fact, I tried to indicate that when we speak about incapacitating and lethal doses, you ask yourselves the question: Is that man going to become so sick he cannot work? Is this man going to die? It is that more gross evaluation I had in mind when I spoke about biological repair, but there is a tremendous amount more to be learned on this factor.

Representative HOLIFIELD. You were speaking of the ability of the spleen to replace white corpuscles, and that sort of thing.

Dr. DUNNING. It is tied up very intimately with the blood picture, the production of white and red corpuscles.

Senator PASTORE. On this very point, how far have our experiments in Hiroshima and Nagasaki gone in proving some of the things you have just developed here?

Dr. DUNNING. I think there is experience in the Japanese data. I think we do have some other limited experiences where others have been accidentally exposed to relatively high doses. In fact, Dr. Graves described briefly his experience yesterday. And we do have evidence of this biological repair factor, especially, as I say, in the blood picture.

There is still a considerable amount to be learned in this, and I will not dare to go much further on this point at this time.

Chairman DURHAM. You are speaking just of the normal repair system, Doctor, by the body, and not by the addition of any medicines. or any type of treatment?

Dr. DUNNING. That is correct.

Senator PASTORE. Would you say that, comparatively speaking, we have not learned a great deal concerning this on experiments on animals in Hiroshima?

Dr. DUNNING. I would not say we did not learn a great deal. Quite the opposite. I will add, too, that every time you learn 1 thing, there seems to be 2 more to be learned. It just opens up whole new avenues of thought and study.

As you well know, most of our work has been done with animals, and then one is faced with extrapolating to man, and this is always uncertain.

Chairman DOUGLAS. Did you participate in that, Doctor?

Dr. DUNNING. No, sir; I did not. Our present knowledge does not permit us to establish a precise overall relationship for the rate of recovery and degree of recovery, but the data seems to indicate that the rate of recovery in man is relatively slow compared with animals.

Therefore, any biological repair factor would have its greater influence where a total given dose is spread out over time rather than the doses that are given rather quickly in time, such as nearby fallout.

Let us pass on, then, to the first of two examples.

One of them is an exercise during the National Association of Civil Defense Directors meeting in Washington, D. C., April of this year, where it was assumed that four bombs were dropped simultaneously, as follows:

A 20 megaton on the Union Station, Washington, D. C.; 5 megaton on the National Airport; 20 megaton on Baltimore, Md.; and 10 megaton on the Patuxent River Naval Air Station. The next chart will give a view of the resultant fallout pattern. (See top of p. 195.)

The units are in roentgens per hour, but in these nearby areas essentially all of the activity is down within 1 hour; so that this is a fairly realistic picture.

These are the numbers, such as 10 roentgens per hour and so on, to 3,000 roentgens per hour.

I would like to call attention especially to the 300 roentgens per hour line, since we will use this for an example in just a moment.

Recalling that radioactive decay is rapid for this early fallout around ground zero, it becomes evident, if adequate protective areas are available, it would be wiser for people to remain indoors, rather than be exposed out of doors, to the out-of-doors dose during this period of highest activity.

Likewise if a delay in movement is possible, there will be more of an opportunity to evaluate the situation, and to then effect an orderly evacuation.

Since each situation is unique, no rigid criteria will be proposed here for permissible exposures or for mandatory evacuation, since there may be other factors present as potentially hazardous as radiation.

This chart was developed to illustrate the kind of thinking and planning possible for civil defense. (See table 2, p. 183.)

Looking now at the 300 roentgen per hour line, we may permit our rescue workers 25, 50, or 100 roentgens, let us say. If we allow our rescue workers only 25 roentgens, that means for them to move into this area and do their rescue work and move out again, they will have to wait until 16 hours after the detonation before they may do so. In that length of time, the populace that were in this area would have received 320 roentgens, and this is based on certain assumptions. This is based on one assumption of rather small protective factors [indicating].

Before the populace is fully evacuated, they would have received 332 roentgens. On the other hand, if we allowed our workers to receive 100 roentgens exposure during the rescue work, they could have moved in at 5 hours instead of 16 hours, after the detonation, during which time the populace would have received considerably less exposure, this [indicating] being again the total exposure, before fully evacuated.

Looking at the last two columns, and especially the last one, it is based on the same situation; only in this case the populace is well sheltered. It is a factor of 10. We assume they are in good protective shelters. I say "good"—a factor of 10. It can be much better than this with well-constructed sheltering.

Even here I think this illustrates the point [indicating]: While they are awaiting rescue, they receive significantly less doses than in the less protected shelter. It is the same context of meaning. If rescue workers are permitted 25 roentgens, the populace will receive 76, as you note here.

Interestingly, if the rescue workers move in early and take the populace out of their relatively well-protected areas into the open, they may receive more exposure here than if they had stayed in place for

the full 16 hours. On the other hand, moving in at 5 hours may be a large advantage for first aid and rescue work, and this sort of thing.

Representative HOLIFIELD. Of course, this makes almost a conclusive argument on behalf of adequate shelter for the people, because, as you note there, if you take them out of the basement where they are getting a factor of 10 percent of the outside radioactivity, they must pass through an outside radioactivity which actually gives them an accumulation of radioactivity more than if they had stayed for, say, a week, in a shelter.

Dr. DUNNING. This is quite possible, although this is not my area of work.

Representative HOLIFIELD. Of course, it does not even compare with the amount the workers would get going into a contaminated area and coming out in a shorter length of time. They would get even more.

Dr. DUNNING. That is right.

Representative HOLIFIELD. That is right. It shows it at the bottom.

Dr. DUNNING. As I say, this is not my area of work. But it just seems to me, in case of emergency such as this, there would be such a chaotic condition that one of the worst things people could do would be to lose their heads and run out of doors, and, in a sense, run around in circles. It would be far better, if they have any kind of protective shelter, to stay put until they know what the situation is like, and then move in an orderly fashion.

Then, in essence, this sort of thinking and planning, I feel, will be most valuable rather than striving to establish any rigid rules or criteria ahead of time.

The second example of the dosage one may receive and the resultant biological effect is for a more distant fallout pattern.

As has been described by Dr. Kellogg and others, there is a wide variability in possible patterns; therefore we can only generalize again.

The next chart is again an idealized pattern. By that, we mean a generalized pattern, because conditions will change from day to day and situation to situation, but if we take a generalized pattern based on the March 1, 1954, high-yield detonation, we see a pattern like this [indicating]. These are expressed in units of effective biological doses, because these incorporate all of the five factors I mentioned briefly at the beginning. These are the best estimates of exposure that people would get if they continue to live in these areas without any special measures of protection. (See top of p. 196.)

Representative HOLIFIELD. What is the time element on that, Doctor?

Dr. DUNNING. Sir?

Representative HOLIFIELD. What is the time element? Is that per hour of exposure?

Dr. DUNNING. This is if they continue to live there for the lifetime of the activity, that is, a period of years, and took no special protective measures, merely went about their daily business. As you can imagine, there are certain assumptions that go into this as to how much time people spend indoors, in what type of buildings, and so forth.

Representative HOLIFIELD. Please repeat the numbers on your chart, because your testimony does not interpret the chart.

Dr. DUNNING. The 50-roentgen effective biological dose line extends out slightly beyond the 400 miles, and this area here [indicating] encompasses about 25,000 square miles.

The 100-roentgen line encompasses about half of that, 12,500 square miles; and the 400 roentgen line about 5,000 square miles.

This is suggestive of a number, 400 roentgens, where the people receive such an exposure that perhaps half would die. The 100 roentgen is suggestive where a few percent might become ill. The 50 roentgen line has no unique significance, but does suggest a number where evacuation should at least be seriously thought of in the face of other hazards.

For those areas downwind, where fallout occurs several hours after detonation, these doses will not be accumulated rapidly. In fact, it will be a period of months, or if you want to go to the end of the curve of doses, it would take a period of years before you would get this full dose. So it would not require immediate emergency measures downwind this far [indicating].

The question is frequently asked as to the time one must spend within a shelter or remain outside of a contaminated area. Again, the answer depends upon what are the permissible levels of exposure, and what are the other hazards one faces if he does move out. But it does indicate that even in the areas of heaviest contamination that one may move in and do a short rescue work, and move out again, if you are willing to permit relatively high exposures to your rescue crew in the order of 100 roentgens.

One then asks the question, How long would I be denied this area? How long before I can go back in there to live?

We assume now they have been moved out. How soon may they move back?

Just taking 4 months later as a point of reference, at 4 months how would this picture look then?

Again, based on certain assumptions, this 50-roentgen line would have shrunk down to an area of about 2,500 square miles, meaning if people move back in here 4 months later and continue to live there indefinitely thereafter in a normal fashion, then they would accumulate about 50 roentgens, effective biological dose.

Then you may extrapolate still further and say, "How about 1 year later? What will this pattern look like then?" Again, it is quite uncertain. But based on certain assumptions again, the 50 roentgen line would have disappeared. In other words, there would be no area in here where people would accumulate 50 roentgens of exposure if they move back in 1 year after the fallout and continue to live there indefinitely.

This does incorporate the biological repair factor, but there are such effects as genetics, as I mentioned, that are linear. In this hottest area it is conceivable there could be several hundred roentgen doses delivered to people who move back in there 1 year later and continue to live there normally.

As I said before, the biological repair factor would bring this down below 50 roentgens, but in terms of genetics, and such aspects, the actual dosage might be several hundred roentgens.

Representative HOLIFIELD. Then this would mean that large areas of land might remain unoccupied for a considerable number of months?

Dr. DUNNING. Yes. But I was about to mention that this is based on the assumption that people do nothing to protect themselves, and nothing to decontaminate the area; simply let it lie there and decay.

Representative HOLIFIELD. It is a very difficult job to decontaminate the large areas of the earth.

Dr. DUNNING. That is quite true. Probably one of the best procedures, if one can afford to do this, is merely to wait and let the activity decay away. But in this area of highest activity which would encompass, perhaps, a few thousand square miles, perhaps measures could be taken on decontamination which would not have to be done in the larger 25,000 square mile area.

Senator BRICKER. What processes of decontamination are available?

Dr. DUNNING. This is a whole subject in itself, sir. I will just briefly mention that the United States Naval Radiological Defense Laboratory in San Francisco have made considerable studies on this subject, and have proposed certain measures of decontaminating buildings and land areas. How effective they are I think is yet to be shown. There has been some experimentation, but I feel a great deal more needs to be done.

Chairman DURHAM. You are speaking primarily to gamma rays now; are you not?

Dr. DUNNING. Yes; this has been completely on gamma rays.

There are other types of rays. The beta rays are of concern, it appears, according to our present data, only when the fallout material comes directly on the skin and remains there for a period of time.

In the case of the fallout of the Marshallese, it was very illuminating to note that even a single layer of cotton clothing was enough to prevent serious beta dose to the skin, and where the fallout material did land on the skin and did remain there, such as in the folds of the neck and in the elbow, there were these so-called beta burns, burns of the skin from these beta rays. Yet, where they had the light clothing on, there were no burns. Nor were there any on even the lower part of the leg, but there were on the feet where again the material had been scuffed up from the ground.

Representative HOLIFIELD. Can you refresh the committee's memory on how many days later this exposure occurred, and how far the place was from the point of detonation?

Dr. DUNNING. The inhabitants of Rongelap Island were about 110 statute miles from the point of detonation. Some were evacuated at 36 hours, and some at about 48 hours after detonation. Upon evacuation, they took baths. Some of them did beforehand, and some of them not. It would appear that those who did take baths in the ocean did not get beta burns. It is merely a physical picture of moving the material from the body.

Representative HOLIFIELD. I referred to that specifically, and I am glad you answered the way you did, because this gives you a chance to answer also in regard to the Japanese fishermen on the *Lucky Dragon* as to how many days later it was they were supposed to have received their exposure.

Dr. DUNNING. They were generally in the same distance, only somewhat closer than the Rongelapese. The fallout occurred on

them, and they did not wash in general. Most of the dose was delivered in the first few days, and so it is a question of getting it off and getting it off fast.

The next topic we will discuss is that of internal exposure which has been mentioned several times before this committee.

The principal hazards from intake of relatively large amounts of radioactive fallout for several weeks immediately following a nuclear detonation are doses one may get to the gastrointestinal tract, to the thyroid, and to the bones.

My written report to this committee considers in detail the amount of ingested fission product activity material required to produce certain radiation doses to these critical organs of the body, and the possible biological effects therefrom.

It is a somewhat long, complicated story, Mr. Chairman, and I would let it go at that, and quote one conclusion, and that is: If the degree of contamination of an area is such that the external gamma radiation may be accepted, for continuous occupancy, then probably the internal hazard would not deny this occupancy.

I think some folks get somewhat confused. They say: "Fine. I think I begin to understand the external doses, but should I drink this water? And should I eat this food?"

As I say, as an overall generalization, this conclusion would appear to be so, but like most of these it is tentative and awaits further information.

Representative HOLIFIELD. There is this one factor I think you will recognize: That in the ingestion of material from the secondary source of vegetables or milk, you would be ingesting the long-lifed element of strongtium 90, and not the comparatively short-lived gamma or beta rays.

Dr. DUNNING. That is correct, sir; and my conclusion took that into account.

Representative HOLIFIELD. Of course, while it might not be lethal, and would not be lethal in the quantities you speak of, it would be residual within the bones or the tissues of the body, and would be a permanent infestation, you might say.

Dr. DUNNING. That is correct. But then one must go from there to the next step, and say, "What is the actual dose delivered to the bones from this internally deposited material?" Because actually there is no significant difference between a roentgen of exposure, whether it comes from strontium 90 or from gamma rays, coming from material lying on the ground.

That is what I put into this conclusion when I said the amount of material that one gets into the body by eating food and drinking water in such an area would be acceptable in the sense that it would be far below lethal amounts. But I think we have to make a distinction in our mind here between peacetime tolerance levels and wartime. I do not have any specific number in my mind, but in these areas where we might permit occupancy in the case of warfare, they would probably accumulate internally deposited materials that would be in excess of our peacetime standards. I think we have to make this distinction.

Representative HOLIFIELD. Is there a distinction between an area that has a hundred roentgens of gamma radiation and its effect upon

the body and, say, the ingestion of 5 or 10 roentgens which remain permanently in the bone now?

Dr. DUNNING. There is very little difference between a roentgen delivered from internal or external sources.

I think, in general, one can make the flat statement that a hundred roentgens, whether it comes from material on the ground or in material you eat, and that goes to the bones, is about the same.

Representative HOLIFIELD. It is a hundred roentgens, but it is not a deposit of strontium 90, which has a persistence over a period of 28 years, while your outside exposure, you might say, to gamma rays or beta rays, would be something that would be temporary in nature and would be subject to repair, where a permanent deposit in the bone marrow would be permanent as far as the half-life is concerned; and, therefore, it would be something that you could not get away from, you might say.

Dr. DUNNING. Yes; I understand. I just repeat that, if we forget the time factor for a moment and simply say that so many roentgens of exposure to the bone, it makes no difference whether you get the hundred roentgens from the gamma rays or from the material in the body. It stays there. Sure, it persists there. What I was saying, as long as it persists, we have the doses year by year by year, and if it all adds up to a hundred roentgens, this is no different, in a sense, from a hundred roentgens of gamma rays, except possibly for the time factor.

Representative HOLIFIELD. This is getting in pretty deep water for me. My thought was that you have a permanent localized area of radiation in the ingestion of strontium 90, where you would not necessarily have a localized concentration of it in the case of allover bodily exposure of a hundred roentgens.

Senator BRICKER. I think there is a misunderstanding generally about the amount of strontium 90 that can be put in the bones from ingestion, because there is only a small percentage of fallout of strontium 90 that goes to plantlife, and only a limited percentage of strontium 90 that goes to animal life, and only a little percentage of that which goes into milk or meat. I think it is something like 6 percent.

Dr. DUNNING. If I may move on, that was my next point here.

Again now we are thinking in terms of warfare, and not in terms of testing.

We have the situation of this March 1 shot, where we have a relatively heavy fallout from a high yield weapon that appeared on the islands in the Pacific. Since then, we have had 10 radiological and biological surveys of these islands. I thought the committee would be interested in a summation of those data, that is, what was the actual contamination of environment in terms of food supply.

I would like to preface by saying that any conclusions are tentative because there are many uncertain factors here, but at least the data suggests in terms of strontium 90 the activity in plantlife in these islands built up over 1 year, that is, it takes time for material to get into the soil, plantlife, and edible parts.

By using rough extrapolations, the data suggests that if plantlife had been growing in the area of heaviest contamination it might have contained 10,000 to 30,000 Sunshine units, at 1 year's time. The corresponding values for the soils are several times higher. Based on

certain assumptions, these data suggest possible levels of strontium 90 in the bones of animals from continuous consumption of this food, of a few thousand to several thousand Sunshine units. Now the maximum permissible body burden for adult atomic-energy workers is equivalent to 1,000 Sunshine units.

There is some confirmatory evidence for this crude evaluation. A variety of native animals were left on the island of Rongelap after the fallout in March 1954. They were collected and sacrificed serially in time. Even after 2 years of continuous occupancy it was reported that there were no pathological changes that could be ascribed to radiation. Their bones contained from about 100 to a few hundred Sunshine units. Since the areas of highest contamination were about 12 to 14 times greater than Rongelap, an extrapolation would suggest values in the same range, that is, if animals had lived in the area of greatest contamination from this fallout, they might have accumulated from a few thousand to several thousand units, of strontium 90 in their bodies.

The Pacific island soils have higher calcium content than most soils in the United States, and, of course, there are differences in the type of plantlife and in the climate. However, theoretical calculations suggest that the same fallout in the United States might result in something like 100,000 Sunshine units in the soils of the United States with the highest contamination. Humans living exclusively off the foods grown in these soils might accumulate a body burden of strontium 90 of a few thousand to several thousand Sunshine units, keeping in mind that 1,000 is the maximum permissible body burden for atomic-energy workers.

Chairman DURHAM. Doctor, the effect of a hundred roentgens from the soil would be no more toxic than the 100 roentgens from the strontium; is that correct?

Dr. DUNNING. As far as the bones are concerned, it is correct. If you receive 100 roentgens from the gamma or strontium, it is essentially the same thing.

Chairman DURHAM. I was thinking of gamma rays.

Representative HOLIFIELD. Let me ask this question on that very point: If the 100 roentgens were ingested, would they not tend to go to certain organs of the body and have a concentrated effect, and, therefore, more of an effect upon, let us say, the liver or the spleen, or some other organ of the body that might be vital to the life of a man, than if the 100 roentgens were spread over the whole body?

Dr. DUNNING. If you could turn that around just a bit, Mr. Chairman. The way we compute it, we asked the question, How much material taken into the body will essentially result in 100 roentgens to the bones, to the liver, et cetera? We start the other way around from what you are saying. We simply ask how much material does one have to take in to end with a 100 roentgen dose. So we have reached our conclusions——

Representative HOLIFIELD. Again, are you not faced with the fact that you could not give a uniform dose of a hundred roentgens to every organ in the body, because some organs of the body—and I am speaking now in the case of ingestion of food or drink—some of the organs of the body would naturally process that, and it would be deposited in those organs rather than in the outside skin and toenails, and so forth.

Dr. DUNNING. That is correct. When we speak of external gamma, we mean essentially that each and every part of the body receives this 100 roentgens.

Representative HOLIFIELD. This I can understand, but I cannot understand how you can ingest contaminated foods or liquids and have it affect the body uniformly.

Dr. DUNNING. I did not mean to say that. If I did, it is incorrect.

Representative HOLIFIELD. You did not say it. I am saying it as a question or a statement for clarification.

Dr. DUNNING. You are quite correct.

Representative HOLIFIELD. Am I right in my supposition?

Dr. DUNNING. You are quite correct.

Chairman DURHAM. What we are saying, Doctor, whether it comes from Sunshine or whether it comes from strontium 90, that is, the gamma ray, it is no different as far as the effect of it, as if the same dose is taken.

Dr. DUNNING. That is correct, sir.

Lastly, then, I would like to mention briefly about the testing, and I do think we have to make a sharp demarcation in our minds that we have up to now been talking about more of a warfare situation. But intimately tied up with this is the testing.

Very extensive efforts are expended to protect the public in the planning of test nuclear detonations, and in the monitoring programs in operation during and between the test series. These are described in a detailed written report to the committee previously.

Since 1951, the United States has conducted 11 series of nuclear tests, 5 at the Nevada test site, and 6 at the Eniwetok Proving Ground for a total of more than 63 test detonations. A sixth series is currently underway at Nevada. So I understood by the report this morning.

The major effects near the testing sites of the fallout was on the inhabitants of some of the Marshall Islands in March 1954, which will be discussed by others, and fallout on the 23 Japanese fishermen. Worldwide effects will be discussed by others.

Since the committee manifested an interest yesterday in the fallout nearby, especially in Nevada, I do have a chart that may be of interest to you. This is our best estimate of exposures in areas around the Nevada test site. The units are roentgens of gamma exposure. They are based on certain assumptions, one of which is that the total dose is this [indicating] if one continues to live there indefinitely. (See bottom of p. 195.)

With those numbers before you, I would like to recall to your mind the recommendations of the National Committee on Radiation Protection and Measurement, and the recommendations of the National Academy of Sciences, which, in lay language, sort of lays the ground rules for our permissible exposures.

Both committees—expressed in somewhat different units, both committees said, in essence, that for individual exposures the maximum permissible amount should be 50 roentgens up to age 30.

Representative HOLIFIELD. At this point, it might be well for you to explain the term "Sunshine unit" in relation to roentgen. Is that not an occupational unit of measurement rather than a general population unit of measurement?

Dr. DUNNING. The Sunshine unit is a coined phrase which is used to express the amount of strontium 90 in relation to the amount of calcium, whether it be in the bones of man, or in the soil or anywhere else. Just like when one buys milk, you have to have some unit. It is merely a coined unit so that one in this business may know how much strontium 90 you are taking about when you say 1 Sunshine unit.

Representative HOLIFIELD. It is not to be confused with a roentgen?

Dr. DUNNING. That is correct. One could mathematically figure out the amount of roentgens 1 Sunshine unit would produce, but it is not the same.

These again are not Sunshine units; these are the more familiar roentgens that we have recently spoken about. So again we say that the maximum permissible exposures for individuals is 50 roentgens up to age 30.

Now, for general populations, which one may define as a million people or more, the maximum exposure from manmade sources, the maximum number recommended is 10 roentgens up to age 30.

So we have for individuals 50 roentgens, and for general population, 10 roentgens up to age 30.

Now, let us look at the records of exposure to populace in these areas.

The highest fallout exposure was in this motor court near Bunkerville, Nev., in 1953, where the people might have accumulated 7 to 8 roentgens of exposure. This might rightfully be compared to the 50 roentgens that I mentioned before as a ground rule.

In terms of general populace around the Nevada test site, I had a little problem finding a million people for a general population, but if one mentally makes larger and larger circles until he encompasses a million people, then the average exposure to the 1 million, is one-tenth of a roentgen for 6 years of testing, which is at the rate of one-half a roentgen per 30 years, which is one-twentieth of the maximum exposures recommended by the 2 committees.

Representative HOLIFIELD. This would be on one test?

Dr. DUNNING. These are all tests. I am sorry.

Representative HOLIFIELD. This is the accumulation of all tests?

Dr. DUNNING. This is the accumulation from all tests; not only Nevada, but all others. This is the sum total.

Lastly, on air and water concentrations, the internal exposure side of the record, I would say this: The highest concentration of activity in the air off the test site in the spring of 1953, the Nevada test site, amounting to 1.3 microcuries per cubic meter of air averaged over a 24-hour period. It was estimated that the radiation dose to the lungs from this activity was less than that delivered every month by naturally occurring radioactive isotopes in the air that we breathe every day.

Representative HOLIFIELD. That is based on an average, but not necessarily a hot spot locality?

Dr. DUNNING. This was the highest concentration of air found in any populated area. There are higher concentration spots on the gunnery range, the control area.

Representative HOLIFIELD. When you speak of normal does that mean sunshine?

Dr. DUNNING. When I said the doses to the lungs?

Representative HOLIFIELD. Yes.

Dr. Dunning. In this room, right in this air, there are naturally occurring radioactive materials. Every time you breathe in you get a certain radiation dose to your lungs.

What I was saying, then, was that by living normally over a period of a month, we have a certain dose delivered to our lungs from this naturally occurring material. Then I compared that with the people who were in this area where the fallout occurred, and said they breathed in the fallout, and then asked how much dose did they receive to the lungs from the fallout. And that is when I made the comparison that the dose from the fallout was less than they would have received each month from breathing naturally occurring substances.

Senator Bricker. That is background radiation principally?

Dr. Dunning. That is correct.

Senator Bricker. Have you anything to say about the effect upon the length of life? I ask that because of animal experimentation. Is there any indication that radiation does shorten life?

Dr. Dunning. This is again a topic in itself. I am not an authority on it, and would prefer to leave it to those who follow.

Senator Bricker. I am advised again there is a witness later.

Dr. Dunning. I think, again, one has to distinguish, though, between chronic and acute doses. There apparently is a significant difference in life shortening effect in large doses delivered in a short period of time versus low doses over a long period of time.

Senator Bricker. Even though there may be some effect from each?

Dr. Dunning. There may be some effect from each. I would leave the conclusion to others on that.

Lastly, how about the water contamination?

Once again, the record says that the highest concentration of activity in water off the controlled area was at Upper Pahranagat Lake, Nev., in the spring of 1955, amounting to 1.4 times 10 to the minus 4 microcuries per milliliter at 3 days after the detonation. This is one-thirty-sixth of the amount considered safe for continuous consumption.

Representative Holifield. Doctor, referring back to your statement on the Riverside motel cabin, what did you say their exposure was there?

Dr. Dunning. Estimated exposure to people, if continued to live there, was 7 to 8 roentgens.

Representative Holifield. We have in the committee record a document prepared in February 1955 by yourself, in which you say:

> In the case of Riverside Cabins, however, the radiological conditions were not ascertained until after the fallout had occured. The maximum infinity gamma dose in the later case was 12 to 15 roentgens.

Have you revised your opinion, or how do you reconcile your two statements?

Dr. Dunning. No, sir; I have not revised it. It is the difference in units. The infinity exposure is on the assumption that people live out of doors 24 hours a day, that there is no effect of weathering and shielding, that the material lies there, neither is lost by wind nor rains, nor does it sink into the ground.

We went back and made a study of that area and of the shielding effects of the homes and of the weathering, and were able to take a series of measurements of dose rate readings, with times, and by this we came up with this estimate of actual exposure of 7 to 8 roentgens. So the difference is in the units. Infinity does mean where they could

not have been any higher than this. In other words, we were giving outside limits, and a complete analysis of the situation led us to believe that the actual exposure would have been 7 to 8 roentgens.

Representative HOLIFIELD. Thank you very much.

Are there any further questions?

We have about 5 minutes. We have a few questions, Dr. Dunning.

If weather and terrain factors cannot be generalized, how reliably can one evaluate the situation at any particular locality? What information do we need to make such evaluation?

Dr. DUNNING. I did not hear the first part, Mr. Chairman.

Representative HOLIFIELD. If weather and terrain factors cannot be generalized, how reliably can one evaluate the situation at any particular locality?

(Discussion off the record.)

Representative HOLIFIELD. Dr. Dunning, will you please answer the question now?

Dr. DUNNING. From a precise scientific point of view this is certainly questionable. However, I think we are faced with the problem of either making our best estimates for planning purposes, or making none. It is on that basis that we have made our best estimates. We simply have said we know something about the effects of winds, we know something about the effects of rains; we will, therefore, try to generalize on what they might be under certain situations.

I do not think anyone is guaranteeing that they will be precisely this way in the case of an actual situation, and the same is true with terrain factors. Again we know some effects of terrain factors. We know the shielding effect of a hill, for example, and the unevenness of the ground as it affects the radiation exposure. Again we must generalize for planning purposes, or not generalize at all. I think that is our choice.

Representative HOLIFIELD. Dr. Dunning, due to the time, we are going to have to adjourn. I am going to hand you three questions here which I would like for you to prepare answers to, and then we will insert them at the conclusion of your testimony.

Dr. DUNNING. I would be delighted to, sir.

(The questions and answers referred to follow, together with a discussion of radiological safety criteria and procedures for public protection at the Nevada test site:)

Question. How was the 450 roentgens lethal dose figure established? What is the range of competent opinion on this number?

Answer. The lethal dose values for humans has been developed primarily from the Japanese data, plus extrapolations from animal experiments. The range of values for LD–50 values (half the people so exposed would die) are roughly from 375 to 650 roentgens. But this range is not as great as these figures might imply. As I have suggested a roentgen of dose as measured in air may deliver different doses within the body, depending upon the geometry of the source. That is, if the radiation is coming primarily from a point source such as the immediate radiation at time of burst, the radiation doses within the body will decrease as the rays pass through. On the other hand in the case of fallout the rays are entering the body from several directions and thus the doses will be more uniform within the body. Under this second set of conditions a lesser number of roentgens as measured in air could produce lethality. The 375 roentgens was estimated on the basis of fallout conditions while the 650 roentgens was for the immediate radiations from the burst.

Question. How constant is the relation between air dose and the biologically effective dose in view of the known gamma radiation energy changes with time?

Answer. It is correct that the energy spectra of gamma radiation dose changes with time and thus will affect the dose distribution within the body and the energy delivered to different parts of the body. Further, the energy spectra at any one time is quite complex, consisting of photons over a wide range of energies, except for long times after a detonation when only a relatively few isotopes remain, such as cesium 137. All of these do complicate the problem of estimating the biological effects. However, there are other variables, such as weathering and shielding and decay constants that have as great or probably greater influence in determining the effective biological dose accumulated.

Question. Compare the numbers derived from the $(\text{time})^{-1.2}$ law decay with that derived from the application of the known gamma emissions from the fission products.

Answer. The relation of $(\text{time})^{-1.2}$ was intended to apply to the actual disintegrations of the atom. We have accepted the rate of beta emissions as closely approximating the actual disintegrations of the atom. However, the ratio of gamma photons emissions to beta emissions varies with time (as does the gamma energies) so that the actual decay of *gamma dose rates* can deviate from the $(\text{time})^{-1.2}$. This deviation probably is not very great until several months after the detonation, when theoretical calculations indicate that the decay is significantly greater than $(\text{time})^{-1.2}$. This is shown in figure 4 of my written report. Of course, presence of any *induced* activity can also result in a departure from $(\text{time})^{-1.2}$.

Discussion of Radiological Safety Criteria and Procedures for Public Protection at the Nevada Test Site *

Gordon M. Dunning, United States Atomic Energy Commission, Division of Biology and Medicine, Washington, D. C., February 1955

INTRODUCTION

The criteria and procedures set forth in the following paragraphs were established after full consideration for protecting the health and welfare of the public, both in terms of radiological exposure as well as possible hazards, hardships, or inconveniences resulting from disruption of normal activities. Criteria are established as guides for the test organization in determining whether any special actions should be taken to protect the public.

With improved methods of predicting fallout and with the use of higher towers for detonating the nuclear devices, it is expected that fallout in populated areas from future tests at the Nevada test site will be less than the highest amounts which have occurred in the past.

Two basic assumptions are made in this report:

(*a*) It is the responsibility of the Division of Biology and Medicine to establish such criteria and procedures for the Atomic Energy Commission as deemed necessary to protect the health and welfare of the general populace from consequencies of weapons tests conducted at the Nevada test site.

(*b*) The operational procedures adopted for meeting these criteria and procedures shall be the responsibility of the test manager, as directed by the Division of Military Application, with the technical guidance of the Division of Biology and Medicine.

The following criteria do not apply to domestic or wild animals since levels of radiation which would be significant to them would have to be higher than those specified herein.

CRITERIA I. EVACUATION

Introduction

The decision to evacuate a community is critical for two principal reasons: One, presumably there might be a health hazard if the personnel were allowed

* This document was based on data and thinking of nearly 3 years ago. Since then the criteria have been revised and are reproduced on pp. 248 through 258. It is planned to revise further these criteria based on additional data and experience gained from operation PLUMBBOB (1957 test series at the Nevada test site).

to remain. Two, there is always an element of danger and/or hardship to personnel involved in such an emergency measure.

It is recognized that extenuating circumstances may accompany any situation where conditions indicate evacuation as a mode of action. The size of the community, areas, and accommodations available for the evacuees, means of transportation and routes of evacuation, disposition of ambulatory cases, protection of the property left behind, and many other factors may enter into the decision relative to evacuation. Further, it is recognized that, under certain conditions, the evacuation of a community might not only prove rather ineffectual but could result in more radiation exposure than if the population remained in place unless the situation be adequately evaluated. A blanket evaluation cannot be made in advance; each situation can be unique. The following criteria therefore are suggested as guides in assessing the possible radiological hazards; the final decision must be made on the basis of all relevant factors known at the time.

Criteria

Table I–a summarizes the radiological criteria to be used in evaluating the feasibility of evacuation.

TABLE I–A.—*Radiological criteria for evaluating feasibility of evacuation*

Effective biological dose [1] calculated to be delivered in a 1-year period following fallout	Minimum effective biological dose that must be saved by act of evacuation (otherwise evacuation will not be indicated)
Up to 30 roentgens	No evacuation indicated.
30 to 50 roentgens	15 roentgens.
50 roentgens and higher	Evacuation indicated without regard to quantity of dose that might be saved.

[1] The "effective biological dose" is an estimate of a biological "damage" dose, taking into account the length of time for delivery of a given dose, and the reduction of dose due to (*a*) shielding afforded by buildings and (*b*) the process of weathering.

The rationale for table I–a is as follows: The total effective biological dose that would be received if evacuation were not ordered is obviously a determining factor. Another consideration is the fact that such an action as evacuation could be dangerous to the individuals and could also possibly be detrimental to a very necessary national effort of weapons development. One must then ask, "Just how much will be gained (radiation dose saved) by evacuation?" Estimates of these two variables are indicated in table I–a. Thus, a populace may receive up to a calculated 30 roentgen effective biological dose in 1 year without indicating evacuation; from 30 to 50 roentgens, evacuation would be considered only if at least 15 roentgens could be saved by such action; and at 50 roentgens or higher evacuation would be indicated without regard to the possible savings in radiation dose.

In making a rough estimate of radiation doses, one may calculate a theoretical maximum infinity gamma dose and then arbitrarily divide by some number, such as 2, for an estimate of dose actually received. Whereas this may be satisfactory as a first approximation, a more accurate estimate should be attempted, especially when dealing with doses that might constitute a health hazard.

Owing to the necessity of making early measurements and decisions, it is to be expected that dose-rate readings, taken with survey meters, will be available evidence at the times of concern. Table I–b summarizes the parameters considered in estimating an effective biological dose based on dose-rate readings.

TABLE I–B.—*Predicting effective biological doses from dose-rate readings*

	A Theoretical maximum dose (based on best estimated rate of decay)	B Biological factor	C Attenuation and weathering factor	D Effective biological dose factor (column B×C)	E Effective biological dose (column A×D)
From time of fallout until time of evacuation	----------	1/1	1/2	1/2	----------
From time of evacuation to time of return [1]	----------	3/4	3/4	[2] 1/2	----------
From time of return to a time 15 days after initial fallout [3]	----------	3/4	3/4	[2] 1/2	----------
From 15 days until 1 year after initial fallout	----------	2/3	1/2	1/3	----------
Total	----------	----------	----------	----------	----------

[1] This estimate is based on the concept that if evacuation were not accomplished, then a certain radiation dose would be accumulated over the period of time selected. This time period also represents the radiation dose saved if evacuation were accomplished.
[2] The value of 9/16 has been rounded off to 1/2.
[3] This assumes that the time of return occurs before 15 days. A period of 15 days was selected to provide a dividing point between the time of initial exposure from fallout to a time 1 year later. The 15 days has not unique significance other than providing a basis on which to estimate the biological factor.

At a later time after fallout, better estimates of radiation doses received may be obtained from film-badge readings or dosimeters. If these film badges or dosimeters are worn on personnel and the evidence of their use supports the view that the readings are a reasonably accurate account of the radiation dose received, then the values recorded on the film badge or dosimeter may be accepted with a correction factor of 3/4 to account for the difference between the dose received by the film badge or dosimeter (including back scatter) and that received at the tissue depth of five centimeters. Table I–c may be used in estimating the effective biological dose from film badge or dosimeter readings.

TABLE I–C

	A Film badge reading	B Biological factor	C Film badge or dosimeter correction	D Effective biological dose factor (column B×C)	E Effective biological dose (column A×D)
From time of fallout until time of evacuation	----------	1/1	3/4	3/4	----------
From time of return to 15 days after initial fallout	----------	3/4	3/4	[1] 1/2	----------
From 15 days until 1 year after initial fallout	----------	2/3	3/4	1/2	----------
Total	----------	----------	----------	----------	----------

[1] The value of 9/16 has been rounded off to 1/2.

Discussion of the biological factor.—As longer periods of time are involved in the delivery of a given radiation dose, lesser biological effects may be expected. From the time of fallout until the time of evacuation probably will be a matter of hours, which has been considered essentially an instantaneous dose, that is, the biological dose factor is 1/1. From the time evacuation could be accomplished to time of return probably would be a matter of several days, so the biological factor has been estimated at 3/4. From 15 days after fallout until 1 year later is essentially a duration of 1 year, so the biological factor has been estimated at 2/3. It will be noted there is no calculation after 1 year, because it is expected under actual conditions of radiological decay and weathering that probably no significant dose will be delivered after a year's time in populated areas around the Nevada test site.

It is recognized that the precise quantities suggested for the biological factor cannot be supported by conclusive evidence. It is reasonable to expect that the delivery of a given radiation dose over a period of many days will have less

biological effectiveness than an instantaneous one (neglecting genetic effects) and that the extension of the period to essentially 1 year should yield a still lower biological factor. One piece of supportive evidence is the work of Strandgvist,[1] where X-ray doses to the skin were factionated into daily amounts, and the biological effects compared to a one-treatment dose. A log-log plot of total doses versus days after initial treatment yielded straight lines. For example, the curve for skin necrosis indicated a ratio of 3,000/6,700 roentgens for a 1-treatment versus 15 daily equally fractionated doses. Of course, daily radiation doses received from fallout are not equally fractionated, so that the ratio would be in the direction of unity. Day-by-day doses delivered from fallout from the 15th day to 1 year are more nearly equivalent than at early times (ignoring the weathering factor). Strandgvist data do not extend beyond 40 days and it is questionable to extrapolate his data in an attempt to derive a similar ratio as above based on 1 year, since other uncertainties are so great, that is, effects of weathering as affecting the rate of dose delivery, and so forth. The ratio would presumably be farther from unity than for a 15-day period. The skin is a relatively rapidly repaired organ and thus may tend to overemphasize the effects of fractionation when considering whole-body gamma doses.[2]

Cronkite reports:[3]

"In the dog, with cobalt gamma rays, the dose that will kill 50 percent of the dogs in a 30-day period when delivered in a single dose at roughly 15 roentgens per minute is approximately 275 roentgens. After this dose of radiation the animals become ill within a period of 7 to 10 days and deaths occur between the 8th and 25th day. Hemorrhage, infections, and profound anemia are prevalent. If the dose is decreased to 100 roentgens per day given over a 14-hour period, the lethal dose is increased to 600 to 800 roentgens. Under both conditions, the animals die in approximately the same period of time with identical manifestations. If the exposure is dropped to 25 roentgens per day given over a 14-hour period, the lethal dose is then increased to well over 1,200 roentgen, and the symptoms and findings are changed."

One problem in such experiments is the evaluation of possibility that the animals may be virtually dead while the exposures are continued. This might be illustrated in experiments using the burro where the daily doses of 400, 200, and 100 roentgens given to 3 separate groups required 3,600 to 4,000, 2,800 to 3,200, and 2,000 to 2,600 total roentgens, respectively, for 100 percent lethality.[4]

Experimental data reported by Boche[5] are summarized below.

Number of days	Dose per day (roentgens)	Dose per week (roentgens)	Survival time (weeks)	Total dose (roentgens)
20	10	60	24	1,440
10	6	36	83	2,988

NOTE.—Unfortunately normal survival times were not given nor were the ages of the animals (dogs).

Blair[6] has taken the two points from Boche's data, inserted these into his (Blair's) equation relating reparable and irreparable damage. The ratio of instantaneous dose to 15-day dose is 350/450 or 0.78, and for 4 months' dose about 350/525 or 0.67.

Blair suggests that "the points are too few to determine the constants (of the equation) with any accuracy but should at least be in the proper range." However, the constants of his equation have checked well with more extensive data on other animals. His equations indicate that the rate of recovery of reparable injury is fastest in the mouse (of the types of mammals selected), about one-half as fast in the rat, and about one-seventh as fast in the guinea

pig and dog, but as Blair pointed out, the reaction of the dog is more representative of the larger, longer lived animals.

Discussion of the attenuation and weathering factor.—From the time of fallout until the time of evacuation it is expected that personnel will be kept indoors. (See criteria II.) Major losses due to weathering cannot be relied upon during this period, so that the estimated factor is 1/2. From the time evacuation could have been accomplished until the time of estimated return it is assumed that personnel will be indoors aboout half of each 24 hours and that major losses due to weathering cannot be relied upon. The overall factor is thus 3/4.

The same reasoning applies to the third period of time, i. e., from assumed time of return to 15 days after fallout.

From 15 days after fallout until 1 year later it is estimated that the attenuation due to buildings and the effects of weathering will yield an overall factor of 1/2.

Dose-rate readings have been taken with survey meters outside and inside of houses around the Nevada test site after fallout occurred. The ratio of readings varied with the type of construction of the house and with the location within the building. Generally, the ratio of readings outside to inside a frame house was about 2/1 with a somewhat greater difference for masonry construction. A limited number of film badges were placed outside and inside of some houses during Tumbler-Snapper and also Upshot-Knothole. In the first case, the difference in total doses was again 2 to 1 or greater, but during Upshot-Knothole only about a 20 percent difference was noted. In fact, in one case during Upshot-Knothole the film badge inside read higher than outside. The differences between these experimental data will have to be investigated during future operations.

The very nature of the weathering factor makes this a difficult paremeter to evaluate. The probability of occurrence of precipitation and/or winds and to what degree has to be estimated, as well as their effects on radiation levels. Leaching effects were studied on soils about 130 miles from ground zero where fallout had occurred during Upshot-Knothole. Dose-rate readings were insignificantly lower than those predicted by radiological decay according to $t^{-1.2}$ after a period of more than 1 year. One example of the effects of winds was observed during Upshot-Knothole. The fallout from the March 17, 1953, detonation was in a long narrow pattern to the east of ground zero. The second day after a fallout a rather strong surface wind blew almost at right angles across the area, for about a period of a day. Dose-rate readings were taken on the first and fourth days at the same locations and then were compared. The fourth day dose rates were less, by factors of 3 to 6, than those to be expected from the first day's readings, based on rate of decay of $t^{-1.2}$. (Other fallout measurements indicated that the rate of decay of this fallout material was not significantly different from $t^{-1.2}$.) Because of the physical conditions described above, these reductions in contamination probably are near the upper limit to be expected from wind.

Operational feasibility of criteria

It is not the intent here to discuss operational procedures, but it should be indicated that the computing of radiation doses as recommended in criteria I is a not too difficult task. If one assumes a $t^{-1.2}$ rate of decay as a first approximation, then a single graph of dose rates versus times after detonation can be constructed that will represent a 30 roentgen effective biological dose for 1 year. An additional family of curves can be made that will provide the answers to the parameters of how much time would be available before evacuation and of how long a time personnel would have to remain out of the radiation area in order to provide for a savings of at least 15 roentgens.

The highest whole-body gamma dose recorded for any locality where personnel were present outside the Nevada test site was at Riverside Cabins, Nevada (about 15 people). following shot No. 7 of Upshot-Knothole. The maximum theoretical infinity gamma dose was estimated to be 12 to 15 roentgens.

CRITERIA II. PERSONNEL REMAINING INDOORS

When the gamma dose-rate reading as measured by a survey meter held 3 feet above the ground reaches the values given in graph II at the times indicated, it is recommended that personnel shall be requested to remain indoors with windows

and doors closed. Release from this restrictive action should be made on the basis of further evaluation of the radiological conditions.

In the event that there be convincing evidence that the radiation levels given in the graph will be reached, it is recommended that personnel be requested to remain indoors before fallout occurs or before the radiation levels equal those in graph II. Release from this restrictive action should be made on the basis of further evaluation of the radiological conditions.

It is recommended that people who had been out-of-doors during fallout of the above magnitude or greater be advised to change clothing and to bathe. The clothing may be cleaned by normal means. While bathing, special attention should be paid to the hair and any exposed parts of the body.

In the event that the monitoring takes place after the fallout has occurred, and extrapolation of the dose-rate readings equals or exceeds those in graph II at the estimated time of fallout, then it is recommended that the same advice be given as in the preceding paragraph.

Discussion

The action of requesting personnel to remain indoors is predicated on the principle that the radiation levels are below those established for evacuation and that this action could reduce the amount of contamination of personnel and reduce somewhat the whole-body gamma dose. (See appendix A for estimates of reduction in whole-body gamma dose.) The actual "savings" healthwise have to be balanced against possible adverse public reaction.

The principal gain in requesting personnel to remain indoors is to prevent or reduce the amount of atomic debris that may actually fall on the body or clothing. Since the peak of fallout usually occurs shortly after the start of fallout, it is important that prompt decisions and actions be taken. Thus, by necessity, the most practical criteria upon which to base a decision are gamma dose rate readings, which are in turn related to the amount of fallout.

Beta dose to skin.—The most immediate solution might be to establish lower permitted dose rate levels at later times after detonation. However, if a series of dose rates are established for increasing times after detonation so that their relationship follows $t^{-1.2}$, then the doses delivered in X hours (before the material is washed off) will be greater for earlier times after detonation. If one were sure of the time that the fallout material was to remain in place, then a scale of dose rates versus time after detonation could be made to yield the same total dose over the X hours. Since there is obviously no set time period for duration of contact that would be valid for all cases, one might assume the worst case where the material remains in place until its activity has decayed to an insignificant level. Dose rates could then be approximated, to yield a given infinity dose, by:

$D=5At$ where: D=infinity dose; A=dose rate at time "t".

If the above discussion is accepted, then the remaining question is to set the infinity dose. Here, we must be clear that whereas the measurements taken by the monitors, and the data upon which action will be decided will be gamma dose-rate readings, the point of principal concern is the beta dose delivered to the basal layer of the epidermis (assumed as 7 milligrams per square centimeter). The ratio of emission of beta to gamma is a function of time after detonation and follows no simple relationship. Further, this ratio at any given time after detonation has not been firmly established. One report suggests the following data:

Time after detonation:	*Beta/gamma*
72 hours	157/1
168 hours	156/1

These data were obtained from a cloud sample rather than actual fallout material, and were a measure of surface dose on a plaque using a "dosimeter type beta-ray surface ionization chamber."

The method of collection suggests the possibility that the thickness of material on the plaques may be less than that to be expected from the amount of fallout that would be of concern when estimating probabilities of beta burns. This would result in a different angular distribution of the betas influencing the beta dose rate in the direction of a higher value for the plaques.

Another report indicates a beta to gamma ratio of 130 to 1 based on theoretical computations. A third report suggests a radically lower ratio; however, there may be some doubt as to its conclusions since the ionization chamber, used to measure gammas only, had a wall thickness of 1 mm. of bakelite which "* * * excluded a small part of the total gamma dose present, as well as a large, but unknown, fraction of the beta." (The range of 0.35 Mev. betas is about 100 mg./cm.^{2} or approximately 1 mm. of bakelite.) For our discussion here, we will assume a *surface* beta to gamma ratio of 150 to 1.

In estimating the beta dose to the basal layer of the epidermis, one may refer to the work of Henriques.[7] He exposed the skin of Chester White pigs to plaques containing different radioisotopes. Pertinent data are abstracted as follows:

Isotope	Energy	Surface dose required to produce recognizable trans-epidermal injury (roentgen-equivalent-beta)	Estimated amount of radiation that penetrated skin to a depth of 0.09 mm. (roentgen-equivalent-beta)
Yttrium 91	1.53	1,500	1,200
Strontium 90	.61	1,500	1,400
Ytrrium 90	2.20		

The average maximum energy of the beta particles from fallout material varies with time but will be assumed to be roughly comparable, in respect to depth dose, to yttrium 91 or Sr–90—Y–90. Since the gamma dose at a depth of 7 mg./cm.^{2} would not be significantly different from the surface gamma dose, the ratio of 130 to 1 for beta-gamma will be assumed at the basal layer of the epidermis.

(One experiment with sheep, using Sr–90—Y–90 plaques, showed that 2,500 reps at the plaques' surface produced ulceration in 1 but not another of 2 sheep.[8] On the other hand, 1,000 rads delivered to tissue depth of 7 mg./cm.^{2} from a P^{32} 1-inch diameter disk (type of animal not stated) produced tanning, prolonged erythema, and desquamation.)

It is to be remembered that the above discussion was first based on *surface* gamma dose rates whereas the monitors will be making their gamma measurements at a height of 3 feet. Past field experience has indicated that the gamma reading from ionization-type survey meters at ground level is about 50 percent higher than at 3 feet. Therefore, if it be assumed that a ground level gamma reading of a survey meter is equivalent to a surface dose rate, the ratio of beta dose rate at 7 mg./cm.^{2} to gamma dose rate at *3 feet* is about 200 to 1.

Another approach to estimating the ratio of beta dose rate at 7 mg./cm.^{2} to gamma dose rate at 3 feet is as follows: Assuming a uniform distribution of 1.0 megacurie per square mile of gamma activity, the dose rate reading from an infinite field is about 4.1 roentgens per hour.[9] Calculations given in appendix B indicate that a like concentration of fallout material will produce about 430 reps per hour at 7 mg./cm.^{2} This suggests a beta to gamma ratio of about 100 to 1 which is about a factor of 2 lower than the first approach. Added support to this latter method of estimating beta doses is found in appendix C.

Such considerations may be fraught with pitfalls. For example, the above discussion implies a uniform distribution of fallout material. Obviously this is not correct, but how far this deviates from the facts and to what extent this influences the results is difficult to assess. Calculations indicate that the production of recognizable beta burns from a single particle requires a high specific activity. (See criteria III for discussion.) It may well be, however, that the particles of fallout are close enough to have overlapping of radiation fields and thus require significantly lower specific activity of the particles to produce beta burns. This hypothesis has support in that even the most superficial beta burns of the natives exposed to fallout following the March 1, 1954, detonation showed a general area affected rather than small individual spots. On the other hand, the cattle and horses exposed near the Nevada test site showed burns over areas only about the size of a quarter. Even though these may not have been produced by single particles, they do represent less of an area effect than suggested for the natives. Also, radioautographs of the fallout in areas outside the Nevada test site suggest the occurrence of individual particles with nonoverlapping of radiation fields. However, in nearby areas where the fallout was relatively heavy, there was a definite overlapping of the fields.

[7] Effect of Beta Rays on the Skin as a Function of the Energy, Intensity, and Duration of Radiation. Henriques, F. W. Laboratory Investigation. Vol. 1, No. 2. Summer 1952.

[9] Effects of Atomic Weapons. 1950.

With our present knowledge it should be stated that due to the particulate nature of fallout it would not be possible to establish reasonable and operationally workable criteria that at the same time would guarantee that there *never* would be an occurrence of a beta burn.

If one were to accept the assumed beta to gamma dose rates of about 100–200 to 1 (measured under the conditions given above), this might mean an infinity beta dose of 1,000 to 2,000 reps to the basal layer of the epidermis when the whole body infinity gamma dose was 10 roentgens. Of course, the fallout material may be removed before the infinity dose is delivered; yet, on the other hand, it is not improbable that it could remain in the hair for essentially this length of time. In the case of a 1-hour fallout, almost one-half of the dose would be delivered in the next 24 hours.

The efficiency of a surface for collecting and holding the fallout material is important. It is not surprising that the highest dose rate readings as well as biological effects were noted on the hair of the natives and also on parts of the exposed body where perspiration was present. Further, it was observed that even one layer of light cotton material was sufficient to protect against beta skin damage in most cases.[10] This was due probably not to the relatively small attenuation of the betas by the clothing but rather to the physical situation of holding the radioactive material at some distance from the skin, which effect would be relatively large.

An added consideration is the possibility of high beta doses delivered to personnel from the fallout material lying on the ground and other surfaces. If the highest degree of contamination considered under this policy is safe when in direct contact with the skin, then the beta dose from an equally contaminated ground will not be hazardous. (See criteria III for discussion on unequal contamination on personnel.) However, it is true that the contamination may exceed the amount to deliver dose rates given in graph II and yet not be great enough to consider evacuation. Some personnel may not go indoors, and those who did will eventually be released from this restrictive action and then may walk around in a relatively highly contaminated area. Because of the more limited range of the beta, the location of greatest concern is the lower legs.

One report estimates a beta to gamma dose rate ratio of about 75 to 1 at 10 centimeters above the ground.[11] Under criteria I it was recommended that consideration be given to evacuation when the gamma dose rate reading at 3 feet was, for example, about 6.2 roentgens per hour at H+3 hours. Roughly, this would correspond to about 575 reps per hour of beta at 10 centimeters. Of course, this activity decays, and also it is presumed that personnel would be sent indoors, at least for a few hours. On the other hand, it strongly suggests that biologically significant doses may be delivered to the feet if not protected. Skin lesions were frequent on the bare feet of the natives evacuated during Castle. This probably was a combination of beta dose from material on the ground and from that scuffed up over the bare feet and then clinging to the skin. (No lesions were observed on the bottom of the feet, undoubtedly due to the thick epidermis.) It would be expected that normal closed-type footwear (as compared to open sandals) would afford adequate protection to the feet from such high beta doses as discussed here. There is still no guaranty that beta radiation from material on the ground will not deliver significant biological doses to the ankles and perhaps lower legs, after personnel are released from staying indoors. For example, if the beta dose at 10 centimeters above the ground is 575 reps per hour at H+3 hours, it would be about 250 reps per hour 3 hours later and 160 reps per hour 6 hours later.

One further possibility is the accumulation of radioactive material around the ankles and lower legs resulting from normal walking about the area. This is discussed under criteria III.

Data on human exposures.—The work of Henriques[12] suggests that at the depth of 0.09 mm. in living porchine skin (maximum thickness of epidermis) that "1,400±300 roentgen-equivalent-beta" (delivered over short periods of time so that they may be assumed to be instantaneous) is required to produce recognizable transepidermal injury. The curve of biological damage rises rather

[12] Op. cit.

sharply so that at a dose of just under 2,000 reps (at 0.09 mm.), the epidermis may be expected to exfoliate and in the majority of cases go on to develop chronic radiation dermatitis persisting for months.

The preceding discussion suggests that, using the gamma dose rates listed in these criteria, which are based on an estimated 10 roentgen infinity gamma does, as high as 2,000 reps might be delivered to the basal layer of the epidermis over a period of time covered by the lifetime of the radioactive material.

There have been instances where the calculated infinity gamma dose in areas where personnel were present around the Nevada test site have reached 12 to 15 roentgens, but there have been no known cases of beta burns in these areas. The number of persons involved in these areas of highest contamination was relatively small, perhaps a few dozen, and with an observed duration of fallout of about 1 hour it is possible that they were not in a position to receive the full fallout. Likewise, minute areas of the skin may have been so affected yet not detected or reported. In other areas encompassing some 2,000 people the infinity gamma dose was about 8 roentgens and no instances of beta injury appeared.

The estimated whole-body gamma dose to natives evacuated from the island of Utirik following the March 1, 1954, detonation at the Pacific Proving Ground was about 15 roentgens for a period of about 3 days, but no beta burns appeared. It is fair to assume here that direct contamination took place due to their mode of living, including housing that was quite open to air currents. Gamma dose rate readings were taken over the bodies of the natives at about H+78 hours both on the beach and after boarding the ship. On the beach the personnel readings averaged about 20 mr. per hour gamma (but this probably included some contribution from the ground contamination), and after wading through the surf and boarding the ship the levels averaged 7 mr. per hour gamma.

The 18 natives on Sifo Island, Ailinginae Atoll, received an estimated whole-body gamma dose of 75 roentgens in about 2¼ days. Of these, 14 later experienced slight beta burns, 2, moderate burns, and none showed epilation.

In the case of the Rongelap natives, the estimated whole-body dose was about 170 roentgens in about 2 days. All 64 natives later experienced beta burns to some degree from slight to severe, and over half of the natives showed epilation from slight to severe.

The 16 natives from Rongelap evacuated directly by air to Kwajalein had personnel gamma dose-rate levels generally 80 to 100 mr. per hour although 1 was as high as 240 mr. per hour and 1 as low as 10 mr. per hour (at H+ about 55 hours). The remaining 48 natives evacuated by ship were reported to have personnel readings that "averaged" 60 mr. per hour before decontamination. The picture is further confused because some of the natives had bathed and some had not before the arrival of the evacuation team.

Most of the 28 United States service personnel stationed on Eniwetok Island, Rongerik Atoll, received about 40 to 50 roentgens, based on film badge readings. Three members of the group who were located for part of the time in another section of the island were estimated to have received somewhat higher doses. Seventeen of the twenty-eight personnel showed only slight, superficial lesions with one questionable case of epilation. It should be pointed out that the personnel were in metal buildings during some of the fallout time and for most of the time thereafter until evacuation. This reduced the direct contamination as well as the whole-body gamma dose. A film badge hanging on the center pole of a tent at one end of the island read 98 roentgens. Calculations based on dose-rate readings at another part of the island indicated somewhat lower doses, if personnel had remained in the open for the period of time from fallout (about H+7.5 hours) to evacuation (at about H+34 hours). Upon arrival at Kwajalein 1 personnel gamma dose rate reading was as high as 250 mr. per hour at about H+35 hours.

The above data do suggest that there may be possible a rough bracketing of gamma-beta doses versus beta burns. On the one hand, the natives from Utirik received an estimated whole-body gamma dose of 15 roentgens and showed no evidence of beta burns. On the other hand, the natives on Sifo Island, Ailinginae Atoll, received about an estimated whole-body gamma dose of 75 roentgens, with 14 personnel showing slight burns, 2, moderate burns, 2, no burns, 3 with moderate epilation, and 15 with no epilation. In addiiton, Rongelap natives received 170 roentgens whole-body gamma dose, and about 90 percent showed some degree of lesions and 56 percent some degree of epilation.

It is to be recalled that: (*a*) The natives probably were out of doors and received the full fallout; (*b*) the oily hair, seminaked, perspiring bodies, including bare feet, and lack of bathing for most, would tend to collect and hold the fallout material; (*c*) the time of delivery of essentially all of the doses was 2 to 3 days. Further, it may be speculated that the fallout on the more distant island of Utirik (about 300 statute miles) would consist of smaller particles and also perhaps lesser possibility of overlapping of radiation fields from these particles.

Some of the relevant data are summarized in table II. Due to the uncertainty of the degree of exposure of personnel on Rongerik to the direct fallout, this group is not included. It is to be immediately emphasized that any comparisons made or implied in the table are at the most only semiquantitative. Table II will be referred to in criteria III and IV but is included here as a summary of the data discussed above.

TABLE II

I	II	III	IV	V	VI			
Location	Estimated time of fallout (hours)	Best estimate of whole-body gamma dose (roentgens)	Skin effects	Personnel reading	Best estimate of average dose rates (mr./hr.) of the islands (taken at 3 feet above the ground) and of natives (personnel readings) after removal from radiation field, both at approximately same time			
					Island	Personnel	Ratio	Approximate time
Rongelap	5½	170	Lesions: 6 none. 19 slight. 22 moderate. 17 severe. Epilation: 28 none. 11 slight. 11 moderate. 14 severe.	(a) Majority: 80–100 mr./hr. at H+54 hours.[1] (b) Average: 60 mr./hr. at H+50 hours. Corrected average: 80 mr./hr.[3]	1300	80	16/1	H+50 hours.
Ailinginae	5½	75	Lesions: 2 none. 14 slight (very superficial). Epilation: 15 none. 3 moderate.	Average: 40 mr./hr. at H+52 hours. Corrected average: 53 mr./hr.[3]	410	53	8/1	H+52 hours.
Utirik	16–18	15	Lesions: None. Epilation: None.	Average: 20 mr./hr. Assumed: 15 mr./hr. at H+78.[4]	110	15	7/1	H+78 hours.

[1] 16 natives evacuated by air to Kwajalein and monitored upon arrival.
[2] 48 natives evacuated by U. S. S. *Philip* and monitored aboard the ship. Data suggest meter readings low by about 50 percent since natives from same island read 80 to 100 mr./hr. at Kwajalein some 4 hours later with calibrated meters.
[3] 40 mr./hr. corrected to 60 mr./hr. according to information in footnote 2. Report did not indicate range of values among individuals nor at different parts of body.
[4] Readings taken by monitors from the *Renshaw* on the Utirik beach where there may have been some contribution to dose rates from land. After wading to ship, average personnel readings were 7 mr./hr.

Data on animal exposures.—The data on animal exposures are less firm than those for humans. Unmistakable beta burns occurred on cattle at Alamogordo in July 1945, on cattle at the Nevada Proving Grounds in spring 1952, and on horses in spring 1953. (The skin damage observed on sheep in the spring 1953 was not established to be beta burns.) However, the exact positions of the animals in relation to known amounts of fallout are not clear.

Following the last detonation of the spring 1952 series at the Nevada Proving Grounds, about one-half of a herd of 150 head of cattle were found to have evidence of beta burns. They were thought to have been 15 to 20 miles from ground zero in Kawich Valley to the northeast and to have been exposed to fallout from the last detonation. Highest dose rate readings taken along a dirt road running lengthwise through this valley integrated to 75 to 100 infinity gamma doses.

During Upshot-Knothole, 16 horses showed skin lesions over the back, and eye damage was noted in a few. The best evidence indicated that the horses were some 10 to 12 miles to the east of ground zero on March 17, 1954, where the fallout occurred from the first detonation (about 15 KT on a 300-foot tower). Radiation levels in this area are not known with certainty, but the fallout occurred in a narrow band and was carried by relatively high velocity winds so that it probably fell on the horses at a time less than 1 hour. If so, probably more than one-half of the infinity dose was delivered during the next day.

Addendum

Since the original discussion above was written, further consideration has been given to the work of Strandgvist and others [13] on the effect of fractionation of doses delivered to the skin and the onset of the observed results. It will be recalled (p. 10) that X-ray doses to the skin were fractionated in equal daily amounts, and the biological effects compared to a one-treatment dose. A log-log plot of total doses versus days after initial treatment yields straight lines.

Basically, this means that as doses are being delivered to the skin a certain rate of repair is taking place. The overall effect might be that higher initial doses from fallout material might be allowed than if one were to integrate the dose over a period of time without consideration for the repair. Because of the difference in shapes of the total beta dose curves for varying times of initial fallout versus Strandgvist X-ray curves the difference between the two curves cannot be expressed as a simple relationship.

Strandgvist quotes a 1,000 roentgen dose in 1 treatment to produce erythema using X-rays (a somewhat smaller number than other data quoted above), 1,250 roentgens if divided into 2 equal daily doses, 1,450 roentgens if divided into 3 equal daily doses, etc. Of course, there are differences between these X-ray doses and beta doses from fallout material, such as differences in doses at increasing depth of tissue and the fact that the X-rays were delivered essentially as an instantaneous dose at intervals of a day while the beta dose rates are assumed to follow the $t^{-1.2}$. However, accepting the assumptions of biological equivalence of these roentgen and beta doses and $t^{-1.2}$, one may then ask the question, "What will the beta dose rates at varying times after detonation that the contamination occurs such that the integrated doses to the skin will at no time equal Strandgvist curve for erythema?"

For early fallout times the limiting factor will be to keep the first day's beta dose below 1,250 reps; for later times of initial fallout the first day dose may be less than 1,250 reps but subsequent accumulative doses may be greater than Strandgvist curve. A family of curves was prepared of beta dose rates versus time after contamination such that each would meet but not exceed Strandgvist curve for erythema for times out to 40 days, then, based on the discussion contained under Criteria I, a conversion factor of 125 was selected to convert beta dose rates at a depth of 7 mg./cm.^{2} of tissue to gamma dose rates at 3 feet above an infinite plane. These gamma dose rates are plotted in appendix C (a).

If one accepts all the assumptions that go into preparing this curve, then one does not have to estimate the variable of how long the fallout material was in contact with the skin, for the curve suggests that as long as the initial indicated gamma dose rates are not reached, then erythema might not be expected to appear. (However, this approach still does not give assurance that *single* hot particles will not produce erythema.)

Generally, the gamma dose rate readings in the curve (appendix C (a)) suggest theoretical maximum infinite gamma doses of about 20 roentgens for a 1-hour fallout, to about 55 roentgens for a 2-day fallout. For those early times after detonation when relatively heavier fallout might be anticipated, this in-

[13] Sievert, Rolf M. The Tolerance Dose and the Prevention of Injuries Caused by Ionizing Radiations. British Journal of Radiology. Vol. XX, No. 236, August 1947.

finity gamma dose is 2 to 3 times greater than the 10 roentgens which was used as a basis of developing criteria II. However, there are two further considerations: One, the interpretation of the data, and certainly the assumptions made in developing the curve in appendix C (a) are open to discussion. Two, if one accepts the interpretations and assumptions it means a safety factor of 2 to 3—not an unreasonable quantity.

Operational feasibility.—Under the criteria recommended in criteria II, there would have been two occasions in the past where personnel would have been requested to remain indoors. Once was at Lincoln mine following the second detonation of Upshot-Knothole where they were so requested to remain indoors for 2 hours and the other occasion would have been at Riverside Cabins (population about 15) following the ninth detonation of the same series. The dose rate reading at Lincoln mine was 580 mr. per hour at H+2. In the case of Riverside Cabins, however, the radiological conditions were not ascertained until after the fallout had occurred. The maximum infinity gamma dose in the latter case was 12 to 15 roentgens.

Personnel were requested to remain indoors (for about 2 hours) following the ninth detonation of Upshot-Knothole. The highest dose rate reading was 320 mr. per hour at H+4.5 hours. This is less than the current recommendations.

CRITERIA III. DECONTAMINATION OF PERSONNEL

Where it is not possible to monitor personnel outside of a general radiation field, it is recommended that an estimate be made of the degree of personnel contamination by determining the location of the individual at the time of fallout. In the event there is uncertainty as to the validity of such an estimate, the assumption will be made that the individual was out-of-doors. In those areas where the infinity gamma dose equals or exceeds 10 roentgens, it is recommended that the individual be advised to bathe and to change clothing.

For personnel being monitored outside the general radiation field where personnel contamination exists over relatively large areas of the exposed body (one-half square foot or more):

> When the reading of a survey instrument held with the center of the probe or center of the ionization chamber 4 inches from the center of the contaminated area equals or exceeds the values given in graph III, it is recommended that personnel shall be advised to bathe and to change clothing.

For personnel being monitored outside the general radiation field, where personnel contamination exists over relatively small areas of the exposed body (less than one-half a square foot):

> The recommended maximum values shall be one-half those given in graph III. Monitoring of the head, arms, hands, lower legs, and feet will be considered as coming under this category. Washing may be limited only to the contaminated parts, and also a change of clothing may not be indicated unless the radiation levels exceeds those stated below concerning monitoring of exterior surfaces of clothing.

For personnel being monitored outside the general radiation field, and the contamination exists over only spots of exposed body (about the size of a half dollar or less):

> The recommended maximum values shall be one-fifth those given in graph III. Washing may be limited only to the contaminated parts, and also a change of clothing may not be indicated unless the radiation levels exceed those stated below concerning monitoring of exterior surfaces of clothing.

For personnel being monitored outside the general radiation field and the contamination exists over any size area on the exterior surface only of the clothing:

> The recommended values under these conditions will be twice those given in graph III. The first recommended action shall be to resort to such simple acts as brushing off the clothing. If this action does not reduce the radiation levels to twice those given in graph III or less, then personnel shall be advised to change clothing and to bathe.

When the general contamination of a community of the degree to produce an estimated maximum theoretical infinity gamma dose of 20 roentgens or greater, personnel who have been out-of-doors at any time during the first 2 days and generally moving around in the area (as opposed to such an act as walking only between a building and a vehicle) shall be advised to brush off the footwear (outdoors), to bathe, and to change clothing as soon as possible after the final return indoors each day. In addition, personnel who go out-of-doors for any length of time during the first 2 days after such a fallout shall be advised to wash their hands at least after the final return indoors each day, and more frequently if possible.

Discussion

Data on humans.—In table II it was suggested that the relative average gamma dose rates from an infinity contaminated field at 3 feet above the ground compared to that on the natives measured by a survey meter held close to the body was:

$$\frac{110 \text{ mr./hr.}}{15 \text{ mr./hr.}} \cong 7/1 \text{ (Utirik Atoll)}$$

$$\frac{410 \text{ mr./hr.}}{53 \text{ mr./hr.}} \cong 8/1 \text{ (Ailinginae Atoll)}$$

$$\frac{1{,}300 \text{ mr./hr.}}{80 \text{ mr./hr.}} \cong 16/1 \text{ (Rongelap Atoll)}$$

It is recognized that there are many uncertainties in estimating such a relationship by this means. Even if one assumes the dose rate readings were taken accurately, the factors involved, especially in relation to the amount of material collected and retained on the body, certainly are not constant. The higher ratio at Rongelap Atoll might have been due to a physical phenomenon where the quantity of material falling per unit area was so great that it was not retained so completely on the body. Even if this explanation is accepted, there still remain many questions.

Theoretical considerations indicate a gamma dose rate ratio at 3 feet above an infinitely contaminated field to that at 4 inches from an equally contaminated field of 6-inch radius to be about 7/1. (See appendix D.)

The sizes of areas and distances from the surfaces were selected independently of any of the information on the fallout on the natives discussed above and were estimates of areas of contamination and distances of monitoring that appeared to be reasonable estimates of these parameters. The close agreement between the gamma dose rate ratios based on theoretical considerations and those observed with the natives is circumstantial. For example, an equally contaminated area of 3-inch radius would yield a theoretical gamma dose rate nearly 3 times less than the selected area of 6-inch radius. In the case of the natives, however, it is believed that they were seminaked, perspiring, and out-of-doors during the fallout, so that it is not unreasonable to expect relatively large areas of the body to be contaminated. In fact, this was noted when they were monitored. By their acts of walking around during the period of fallout and sleeping on mats that were heavily contaminated it would seem possible that significant areas of the bodies of the Ailinginae and Utirik natives could be as heavily contaminated as was the ground. (It is unknown if there were sufficient winds that might have raised the material from the ground to the body after fallout occurred.)

There is further uncertainty of what is meant by the monitor's report of "average" personnel readings. The dose rate readings in the hair are known to have been significantly higher than the rest of the body in most cases. It is unknown how these readings were "averaged."

Whereas these data certainly are not firm enough for one to place great confidence in the precise quantities of the ratios of 7/1 or 8/1, they do indicate the obvious fallacy of accepting a 10-roentgen infinity dose based on gamma dose rates measured on personnel outside the radiation field. For example, the natives from Ailinginae showed personnel dose rates readings that would approximate 9 roentgens (gamma) in 2¼ days, and yet skin damage to some degree was evident in 14 out of 16 of the personnel. On the other hand, the natives from Utirik showed no skin damage, with an estimated 2.2 roentgens in 2½ days based on gamma dose rates measured on personnel. The uncertainty of these data was discussed under criteria II. They do suggest, however, that if the contamination of a relatively large area of the exposed body produces less than 1 roentgen infinite gamma dose as measured by a survey meter held 4 inches from the surface there is a large probability that beta burns will not result. (See also discussion under criteria II.)

Doses from small sources.—When the same dose rate reading is produced at a given height above a surface from a smaller area, the amount of contamination per unit area is greater (other factors being equal). Therefore, it would seem desirable to reduce the recommended dose rate levels when relatively small areas are involved. It is recognized that radiation from another nearby spot may

contribute to the survey meter reading when monitoring a small area on personnel, but this has not been taken into account, first, because of the difficulty of establishing a prior appraisal of this variable factor and, second, whatever this contribution may be it will now become an added safety factor.

Of course, the problem is still complex, because when considering smaller and smaller areas the eventual end point is a single particle. An estimate of beta doses at the surface of an imaginary sphere surrounding a fallout particle is given in appendix E and an estimate of beta doses from a single particle required to produce recognizable erythema is presented in appendix F. Calculations indicate that the specific activity of some individual particles found in fallout would be great enough to produce recognizable erythema if held in contact with the skin for less than 1 day, yet the gamma dose rate reading at 4 inches may be relatively small. (See appendix G.)

Additional information on doses from individual particles has recently been reported.[14] The particles found in and around Hanford consisted principally of three radioisotopes, Ru-103, Ru-106, and its daughter Rh-106. The data and calculations in appendix H also strongly indicate that a single fallout particle could produce a recognizable erythema.

Contamination of clothing.—In the case of contamination of clothing, higher dose rates might be tolerated than those for exposed parts of the body. This was exemplified in the natives where no beta burns were observed under clothing of the most highly contaminated personnel. (This does not include such areas as under the waist line where material apparently collected and was held in place.) On the other hand, very large increases in contamination should not be tolerated since it is possible for the clothing to be rearranged so as to bring the contaminated surface in contact with the skin. Further, it is not unlikely that one may rub his hands over his clothing and then through the hair where the material could be held in place for relatively long periods of time.

Beta exposure to the hands.—A further consideration is the beta dose to the hands resulting from handling objects contaminated with fallout material. Although some data are available on beta burns from handling radioactive objects, the conditions are so different from those associated with fallout that comparisons probably would not be valid.[15]

If the above assumptions and calculations are correct concerning contamination of a general area from fallout, then the transfer of all the radioactive material to the hands from an object of equal area would not constitute a hazard. Thus, one might consider using as criteria for monitoring objects, the dose readings given above for monitoring personnel outside the general radiation field. However, the problem is more complex, since the hands may come into contact with contaminated surfaces many times larger in area than the hands, with an undetermined percentage of activity being transferred to the hands. Of course, an added uncertainty is the frequency of washing of the hands and/or the rubbing off of the material from the hands.

Further, one might speculate that a given surface could have significantly higher contamination than the general area and that the handling of such a surface could constitute a greater risk. This might be true because of the greater amount of activity transferred to the hands or because of the doses delivered during the time of actually handling the object. The uncertainty of the percentage of transfer of material has been mentioned. One uncertainty in the second case is the length of time the object would be handled.

Based on calculations in appendixes B and D, when an object is held in a hand, a rough estimate of the ratio of dose rates of beta to the basal layer of the epidermis to that of the gamma reading on a survey meter held 4 inches away from an object 2 inches in radious (outside a general radiation field) might be 5,000 to 1 (appendix I). Thus, if this object were contaminated with the same activity per unit area that would produce an infinity 10-roentgen whole-body gamma dose from general contamination of the area, it would produce about 50 mr. per hour gamma at 4 inches away at H+1 hours, and about 250 reps per hour at a depth of 7 mg./cm.^{2}. Since the palms of the hands have an approximate epidermal layer of about 40 mg./cm.^{2} the beta dose to the basal layer would be about 170

[14] HW-33068. A status report. September 15, 1954.
[15] Beta Ray Burns of Human Skin. Knowlton et al., The Journal of the American Medical Association, vol. 141, No. 4. September 24, 1949.

reps per hour. (The time of H+1 was selected to show about the highest magnitude of dose rates.) If one assumes that the decay is according to $t^{-1.2}$, then the total beta dose to the basal layer of the epidermis of the hand in the next 10 hours would be about 320 reps.

Whereas the above estimates do not indicate an alarming situation, a more serious problem may come when the contamination is just less than that where evacuation is indicated. For example, the contamination of the general area may be 5 or 6 times that used as an illustration in the preceding paragraph, without evacuation being recommended. Thus, beta dose rates from handling objects, especially in times soon after fallout, may be high enough to be a problem. A simple and expedient procedure to reduce this factor is frequent washing of the hands after handling objects that were in the fallout.

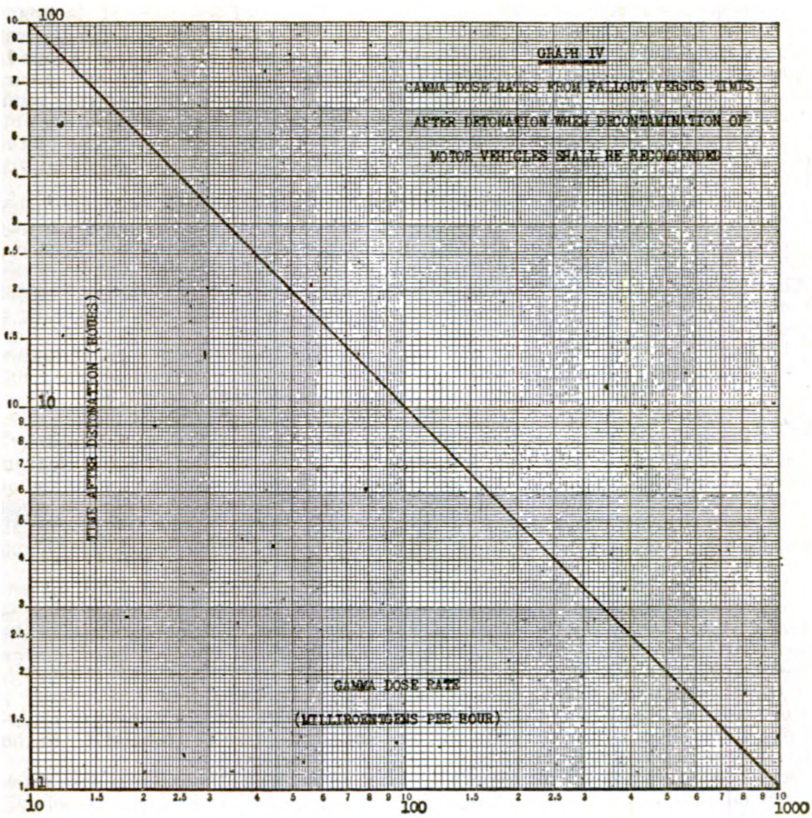
Beta exposure to the feet and lower legs.—It was suggested in criteria II that normal closed-type footwear (as compared to such as open sandals) would probably afford adequate protection against significant beta doses to the feet from fallout material on the ground. There is still the added problem if the material be scuffed up and cling to the ankles and lower legs. If there were no intervening clothing, or perhaps even with thin stockings or socks, this might result in significant biological beta doses being delivered to these parts. For example, if the gamma dose rate reading at H+3 hours were something less than 5 roentgens per hour, evacuation would not be indicated. However, for fallout material of the same concentration in contact with the skin the beta dose rate at 7 mg./cm.^{2} would be about 600 reps per hour. (See appendix B.) Presumably, personnel would be kept indoors for a few hours, but upon release the approximate beta dose rates at 7 mg./cm.^{2} would be 260 reps per hour 3 hours later, or 210 reps per hour 6 hours later. In addition, there is the variable factor of what concentration of fallout material may accumulate in the ankle region by walking around an area.

A concentration of fallout material on the ground that would result in about 20 roentgens maximum theoretical infinity gamma dose if in contact with the skin, would result in a beta dose rate to the basal layer of the skin of about 1/4 those indicated in the previous paragraph.

CRITERIA IV. MONITORING AND DECONTAMINATION OF MOTOR VEHICLES

It is recommended that when the predicted fallout across a main highway will be equivalent to a 10-roentgen infinity gamma dose or higher, vehicles be held until after the actual fallout has essentially ceased. They should be then warned to proceed with windows and air vents closed, and the cars should be monitored after passing through the contaminated area. When 5 to 10 roentgens are predicted across a main highway, vehicles should be warned to proceed with windows and air vents closed and should be monitored after passing through the contaminated area. Monitoring and warnings should be continued until there is reasonable belief that no or very few additional vehicles will exceed the values given in graph IV.

When the dose rate reading taken inside a vehicle, or taken over any exterior area that is readily accessible, equals or exceeds the values given in graph IV, the vehicle shall be cleaned inside and outside. Exterior areas to be monitored should include the wheels and under parts of the fenders but not the under carriage. The survey meter should be held approximately 4 inches from any surface.



Discussion

In the past, fallout has occurred across highways in significant quantities. Table IV–b below indicates some pertinent data during Upshot-Knothole.

TABLE IV–B

Shot No. (chronological)	Approximate yield (KT)	Tower (feet)	Time of fallout (hours)	Estimated dose rate reading of highway at time of fallout (mr./hr.)	Location	Approximate distance from ground zero (miles)
1		300	1¼	920	30 miles south of Alamo on Highway No. 93.	60
1		300	2¾	260	1 mile north of St. George, Utah.	130
6		300	5	325	Junction of U. S. Highway No. 91 and Nevada Highway No. 40.	80
7		300	4½	760	20 miles northwest Glendale, Nev., on Highway No. 93.	65
7		300	7	400	8 miles west of Mesquite, Nev., Highway No. 91.	105
9		300	2	1,000	36 miles north Glendale on Highway No. 93.	60
9		300	3¼	420	St. George, Utah, Highway No. 91.	130

Road blocks were established on Highways 93 and 91 following shots Nos. 7 and 9 of Upshot-Knothole. The highest reading on a private automobile was 100 mr./hr. (gamma) inside and 110 mr./hr. outside at H+3½ hours. About 75 cars were washed (roughly one-eighth of the total monitored). All of the cars that were washed, except the one mentioned above, had outside dose rate readings less than half of the highest. The ratio of dose rate readings on the outside of the car to inside varied from unity to about 4/1. Probably one of the important factors here is the difference between driving with windows and/or ventilators opened or closed.

One bus read 250 mr. per hour outside and average of 100 mr. per hour inside with a high inside reading over the rear seat of 140 mr. per hour at H+8¾ hours.

Considering the amount of time one normally spends in an automobile, these dose rates do not necessarily represent a health hazard in terms of gamma doses. What is probably a more limiting factor is the direct contamination one might acquire by rubbing against the outside of the car, especially when changing a tire.

It is assumed that monitoring will be accomplished outside a general radiation field. Theoretical calculations (appendix D) indicate that gamma dose rate readings taken at 4 inches from a surface will be 51 percent, 42 percent, and 27 percent of those by a meter at 3 feet above an equally contaminated infinite field when the radii of contamination are resjectively 3 feet, 2 feet, and 1 foot.

These data suggest that when the gamma dose rate reading at 4 inches from a generally contaminated car is about one-half that for an infinite plane taken at 3 feet, the degree of contamination per unit area will be about equal; and when the wheels are being monitored ½ to ¼ of a gamma dose rate reading will represent equivalent contamination (depending on the gamma contribution from the body of the contaminated vehicle).

Another factor to be considered is that the probability of collecting fallout material on the body from a generally contaminated area in which one lives is greater than from one's automobile. On the other hand, it has been noted in the past that significantly higher amounts of contamination have been found on the tires and under parts of fenders than on the remainder of the car. (Undoubtedly, this is a simple phenomenon of picking up the activity from the highway.) It one were to change a heavily contaminated tire, significant amounts of radioactive material might accumulate on the hands, and later be transferred to the hair or eyes by a simple rubbing of the hands over those parts.

A comparison might be made here between recommended maximum dose rates found on personnel and the establishing of levels of activity for automobiles. There is one obvious difference, howewver; in the first case the material is already on the person while in the second case one has to introduce the factor of probability of transfer of contamination (and to what degree) from the car to the body.

The dose rates (measured as stated) in graph IV would represent about equal contamination per unit area for a car as for an infinite plane if the car were rather uniformly contaminated. If the activity were confined, say, principally to the tires and under parts of the fenders, the dose rate readings might represent nearly twice the degree of contamination. One must weigh this condition with the probability that a tire will be changed before he activity has decreased significantly.

A given dose rate reading inside a vehicle may represent less contamination per unit area due to the contribution of gamma radiation from the exterior of the vehicle. On the other hand, contamination within a vehicle would more probably be picked up by personnel than if it were on the outside. Further, it is recognized that significantly high concentrations of radioactive fallout may accumulate in such parts as the air filters of an automobile. Again, this has to be weighted against the probability that they will be handled before the activity has decreased to low levels plus the fact that it is relatively difficult to monitor such parts on a mass basis. The uncertainties present in estimating possible hazards from vehicle contamination would not justify fine distinctions in monitoring the various parts. A thorough cleaning, inside and outside, would appear to be the best solution.

One of the obvious ways to avoid much of the problem discussed in criterion IV is to prevent vehicles entering an area during the time of fallout. This will not prevent the first vehicles passing through from picking up activity on the tires from the highway. It is believed, however, this will not constitute such a troublesome problem and past experience has indicated that the activity found

on the tires noticeably decreased after several cars had passed over the highway. Further, if vehicles are not present in the fallout it will help reduce contamination of the passengers and of the insides of the vehicles.

Operational feasibility.—In the past, the criteria used for washing cars has been 7 mr./per hour, and at a later time 20 mr./per hour (gamma), inside a vehicle. This resulted in washing about 75 cars (roughly one-eighth of the total monitored) following the seventh and ninth detonations of Upshot-Knothole. Under the recommendations given in criteria IV, the bus mentioned above, but probably none of the cars, would have been washed.

The data given in graph IV–b indicate that if these radiation levels given had been predicted before the fallout, Highways Nos. 91 and 93 would have been closed prior to the fallout from the seventh detonation and possibly Highway No. 93 for the ninth detonation.

CRITERIA V. CONTAMINATION OF WATER, AIR, AND FOODSTUFFS

In any area where the theoretical gamma infinity dose exceeds 10 roentgens, adequate sampling of the water, air, and foodstuffs should be made to ascertain the conditions of possible contamination. Based on past data, however, it is not expected that under those conditions of fallout, where the radiation levels are below those stipulated for possible evacuation, that the degree of contamination will be a health hazard. (Nor is it implied here that any level above this does constitute a serious contamination of water, air, or foodstuffs.) Therefore, it is recommended that no action be taken in regard to limiting intake except to advise the washing off of such exposed foods as leafy vegetables when that action seems desirable.

Discussion

Water.—Table VI–A lists the six locations having the highest concentrations of fission products in water sources during Upshot-Knothole, and for comparative purposes the estimated external theoretical maximum gamma infinity doses.

TABLE VI–A

Locality	Concentration (microcuries per milliliter extrapolated to 3 days after detonation)	External theoretical maximum wholebody gamma infinity dose (roentgens)
Virgin River irrigation canal, Nevada	8.7×10^{-5}	6.0
Irrigation ditch, 56 miles north of Pioche, Nev	4.5×10^{-5}	.15
Lower Pahranagat Lake, Nev	3.2×10^{-6}	2.0
Virgin River at Mesquite, Nev	2.6×10^{-6}	2.5
Bunkerville, Nev. (tap water)	1.2×10^{-6}	7.0
Crystal Springs, Nev. (tap water)	1.1×10^{-6}	.15

Due to weather and to attenuation of the gamma rays by buildings, the wholebody gamma dose estimated to have been actually delivered was probably closer to one-half of the values shown.

The maximum permissible concentration of fission products in drinking water is $5 \times 10^{-3} \mu c$/ml. extrapolated to 3 days after detonation. This is considered a safe concentration for continuous consumption.

Whereas, the monitoring of water sources is of value for documentary purposes it should be recognized that the concentrations found may vary widely within small geographical areas and even at the same location at different times (taking into account radioactive decay). Thus, confidence cannot be placed in precise values. Table VI–A suggests that even if one were to have stored up the water listed at Virgin River Irrigation Canal and subsisted entirely on this for a lifetime, the concentration would be about 58 times less than the maximum permissible amount. Normal factors of dilution by additional rainfall and/or by the influx of lesser contaminated ground water would be expected to reduce the level of activity.

Air.—Considerable effort has and is being made to evaluate hazards from airborne radioactive materials, including fission products. There are certainly many unanswered problems including the possible hazard from a single particle in

the lungs. Despite the uncertainties and as yet incomplete analysis of the inhalation hazard, the preponderance of evidence today is that the external gamma hazard from fallout is the more limiting factory of the two.[16] (However, see discussion on food contamination.)

During Upshot-Knothole quite complete data were collected of concentrations of airborne activity on about 150 occasions in some 40 different localities within 200 miles of the Nevada Proving Grounds. These included monitoring of all detonations. Histograms were made of air concentrations versus time after detonation for 30 occasions and estimates were made of doses to the lungs. These data for the five communities showing the highest air concentration are given in Table VI–B. The histogram for St. George (the highest 24-hour average concentration of fallout ever measured in a populated area) is reproduced in appendix J.

TABLE VI–B

Locality	24-hour average concentration (microcuries per cubic meter)	Dose to lungs (13 weeks) based on 20 percent deposition and 100 percent retention thereafter (mreps)[1]	Theoretical maximum whole-body gamma 13-week dose (roentgens)
St. George, Utah	1.29	130	3.5
Lincoln Mine, Nev	4.0×10^{-1}	12	1.5
Mesquite, Nev	1.7×10^{-1}	13	1.0
Groom Mine, Nev	3.4×10^{-2}	7	0.35
Pioche, Nev	2.0×10^{-2}	3	0.015

[1] The method used in estimating doses to the lungs is given in appendix K.

The criteria previously established by an Ad Hoc Jangle Feasibility Committee (Washington, D. C., July 13, 1951), for air concentrations were—

"At a point of human habitation, the activity of radioactive particles in the atmosphere, averaged over a period of 24 hours, shall be limited to 100 microcuries per cubic meter of air (corresponding approximately to a ground level gamma intensity of 30 mr. per hour).

"The 24-hour average radioactivity per cubic meter of air, due to suspended particles having diameters in the range 0 micron to 5.0 microns, shall not exceed one-hundredth of the above; nor is it desirable that any individual particle in this size range have an activity greater than 10^{-3} microcuries calculated 4 hours after the blast."

In the January 20, 1954, meeting of the ad hoc committee the basis for recommending the above air concentrations was discussed. Essentially, these criteria was selected by estimating the gamma dose that might be delivered by the passing of a radioactive cloud. Since there are better methods of estimating gamma doses and since there are uncertainties in evaluating the hazards of such transitory air concentrations as experienced from fallout, and since the preponderance of evidence from past nuclear test series indicates that the external gamma hazard is more limiting than the inhalation one, it was recommended in the January 20, 1954, meeting to strike from the record the past recommendations for maximum permissible air concentrations. It was recommended that an air monitoring program be continued for documentary purposes and for whatever value the data might have in the future when new analyses might be made in the light of additional knowledge.

A further discussion of the single particle problem may be made. In arriving at the recommendation" * * * nor is it desirable that any individual particle in this size range have activity greater than 10^{-3} microcuries calculated 4 hours after the blast" a computation was made that the average radiation dose from such a particle to a sphere one-half a millimeter in radius would be 385 reps.[17] However, the conclusions may be misleading. In the case of a single particle, relatively large doses are delivered near the particle and small doses at a greater distance. Appendix L suggests one possible estimate of this phenomenon. The

[16] Ad hoc committee meeting. Washington, D. C. Jan. 20, 1954.
[17] Minutes, Meeting of Committee to Consider the Feasibility and Conditions For A Preliminary Radiologic Safety Shot for Jangle. LASL. May 21–22, 1951.

parameters involved here are many and difficult to evaluate. For example, how long will a particle remain in one place in the lung and what dose will be delivered during that time?

It has been suggested that in the upper respiratory passage 20-micron diameter particles are the upper limit of size for deposition and that "Cilia sweep 4 to 6 cycles per second. The probability of a particle remaining within 1 millimeter zone for as much as one-half hour appears to be vanishing small. * * * Protection will also be provided by the mucus lining which is itself renewed several times an hour." Accepting the estimates above and the methods illustrated in appendixes E and F, it may be computed that about 8 reps would be delivered to the surface of an imaginary stationary sphere 1 millimeter in radius by a 20-micron particle (0.5 microcurie) in 30 minutes (appendix L). Larger doses will be delivered closer to the particle but with the relatively rapid movement of the particle, it does not appear that large doses will be delivered to a great number of cells. Multiple exposures might occur from additional particles but again this risk is difficult to evaluate.

Food.—Considerable effort is being directed toward the study of contamination of food from fallout. One element of major concern is Sr–90. It has been estimated that if one were to subsist entirely on food grown from soils containing about one-tenth to 1 microcurie per square foot of Sr–90 (1,000 pounds of calcium per acre to an average depth of 6 to 7 inches), that over a period of years there would accumulate in the human skeleton a body burden of 1 microcurie of Sr–90.[18] The highest Sr–90 activity found in soils from agricultural areas, about 100 miles from the Nevada test site, now shows a concentration of about 3.4×10^{-3} microcuries per square foot. This is a factor of 30–300 times less than the one-tenth to 1 microcurie of Sr–90 quoted above. The calcium content of soils around the Nevada test site is several times greater than the 1,000 pounds per acre used as a basis for calculations, which would materially reduce the strontium uptake.

(Although not of direct concern to the Nevada test site, it is of interest to note that soils were collected from the Marshall Islands following the fallout in early March 1954. Appendix M summarizes these data.)

A recent report strongly suggests that contamination of leaf surfaces followed by either direct consumption or intake by way of milk is a far more important pathway of intake than the soil-plant-animal cycle, at least for those times of year when plants may be in a state of growth to collect the fallout. Further analysis is being planned.

This same report raises a new problem. Based on stated assumptions, the data presented indicate relative doses of:

thyroid: tens of thousands of reps
Sr^{89-90}: 300 reps
external gamma: 40 roentgens

High radioiodine doses to the fetus and baby may be particularly important. Additional evaluation will be given this problem.

CRITERIA VI. ROUTINE RADIATION EXPOSURES

The whole-body gamma effective biological dose for off-site populations should not exceed 3.9 roentgens over a period of 1 year. This total dose may result from a single exposure or series of exposures.

If integrations of dose rate readings are used in estimating the effective biological doses, then table V may be used.

TABLE V

	Multiplication factor	Effective biological dose
Maximum theoretical radiation dose from time of fallout to 15 days later	¾	
Maximum theoretical radiation dose from 15th day to 1 year	½	
Total (best estimate of effective biological dose)		

[18] Private communication, L. A. Dean, U. S. Department of Agriculture, Beltsville, Md., April 28, 1954.

If film badges or dose meters are worn on personnel and the evidence of their use supports the view that the readings are a reasonably accurate account of the radiation dose received, then the values recorded on the film badge may be accepted with a correction factor of ¾ to account for the difference between the dose received by the film badges or dosimeters (including backscatter) and that received at the tissue depth of 5 centimeters.

CRITERIA VI. ROUTINE RADIATION EXPOSURES

Discussion

In 1953 the following recommendation was made in the report of Committee To Study Nevada Proving Ground:

"It is recommended, and found to be in conformity with the present principles of determining permissible exposure limits, that for test operation personnel the total body gamma exposure be limited to 3.9 r. in 13 weeks, and that the same figure be applied to the off-site communities with the further qualification in the latter case that this is the total figure for the year. In general, this implies a single test series in any given year."

On the basis of this recommendation and the reasoning discussed under criteria I, the criteria for estimating the whole-body gamma effective biological dose are summarized in table V. It will be noted that the biological factor included under criteria I is omitted in criteria V. In the first case we are dealing with relatively high doses that may require emergency measures with their attendant hazards. It is a situation where one wishes to estimate all pertinent factors in evaluating radiation doses even though they may not be known with preciseness, before recommending an emergency action that may produce greater problems. In the case of criteria V one is concerned with relatively lower doses during routine operations. It would be difficult to justify on the one hand the proposition that weekly doses for general populations may be integrated and taken in a single exposure without penalty and on the other hand, that a given dose received over a period of a year may be administratively reduced because of biological repair. Therefore, the biological factor is omitted.

The general effects of backscattering on measured radiation doses are fairly well established. Further, knowledge of depth (tissue)-dose curves has advanced to a quantitative state.[19] Thus, there seems to be little doubt that a film badge or dosimeter worn on the person will overestimate the gamma radiation dose delivered at a depth of 5 centimeters (assumed depth of blood-forming organs). A major factor in determining this difference is the quality of radiation under consideration. One report dealing explicitly with radiation in a fallout field suggests a factor of about ¾.

---

[19] Permissible Dose From External Sources of Ionizing Radiation. National Bureau of Standards Handbook 59. September 24, 1954.

APPENDIX A. SAMPLE ESTIMATION OF GAMMA DOSES SAVED BY REMAINING INDOORS

EXAMPLE I

Assume: Time of fallout = H + 3 hrs
Dose rate at H + 3 = 667 mr/hr

Then: Theoretical maximum dose from time of fallout to 3 hours later --- 1.30 r
Savings by remaining indoors for 3 hours --- 0.65 r
1 year effective biological dose if personnel did not remain indoors during the 3 hours (based on same assumptions contained in section on evacuation) --- ~5.5 r
Percent of 1 year effective biological dose saved by remaining indoors for the 3 hours --- ~12

EXAMPLE II

Assume: Time of fallout = H + 3 hrs
Dose rate at H + 3 = 667 mr/hr

Then: Theoretical maximum dose from time of fallout to 8 hours later --- 2.30 r
Savings by remaining indoors for 8 hours --- 1.15 r
1 year effective biological dose if personnel did not remain indoors during the 8 hours (based on same assumptions contained in section on evacuation) --- ~5.5 r
Percent of 1 year effective biological dose saved by remaining indoors for the 8 hours --- ~21

APPENDIX B. *Calculations of Beta Dose Rate at Depth of 7 Milligrams per Square Centimeter From a Thin Extended Source*

Assume: 1.5 Mev Beta (mean energy = 0.5 Mev)
$\mu = 10$ cm²/gm

(This assumes a single mass absorption coefficient.)

$$N = No\ e^{-\mu x}$$

where
No = number of betas at surface per cm² per sec.
N = number of betas at depth x
μ = mass absorption coefficient
x = distance (depth) under consideration

$$\frac{dN}{dx} = -\mu No\ e^{-\mu x}$$

$$R = \frac{\mu No\ e^{-\mu x} E}{2}$$

where
R = dose rate at depth x
E = mean energy of betas

$$R = \frac{(10) No\ e^{-(10)(0.007)} (0.5)}{2} = 2.33\ No \text{ Mev/gm-sec.}$$

$No = 3.7 \times 10^4 C$ where: C = activity in microcuries per cm²
$R = 8.65 \times 10^4 C$ Mev/gm-sec.
$R = (1.39 \times 10^{-1})(C)$ ergs/gm-sec.
$\cong 5.4\ C$ reps/hr
or $\cong 5.0\ C$ rads/hr

Example

Assume: $C = 80 \mu c/\text{cm}^2$ (beta)
$R = 5.4\ C$ where: R = dose rate at depth 7 mg/cm² in reps
C = activity/cm² in μc

$= (5.4)(80)$
$= 432$ reps/hr
or $= 400$ rads/hr

Comparison Beta Dose Rate (Reps/hr) at 7 Mg/cm² to Gamma Dose Rate Measured in Infinite Field at 3 Feet Above the Surface

Assume: 80 $\mu c/cm^2$ (beta), equivalent to 1 megacurie/mi² (gamma)

$$\frac{432}{4.1} \cong 105$$

APPENDIX C. *Experimental Data Versus Theoretical Calculations (Appendix B) in Estimating Beta Doses*

In one relevant experiment, a thin P^{32} source was prepared by soaking a filter paper in a solution of phosphates and allowing it to dry. The surface dose rates were then measured with a surface ionization chamber.[1] Pertinent data are abstracted as follows:

Thickness of source	9.6 mg/cm²
Activity of source	77.0 $\mu c/cm^2$
Surface dose rate	0.127 rep/sec; 457 reps/hr
Dosage rate at depth of x centimeters	$e^{-9.5x}$

A. Theoretically:

Using the equation from Appendix B

$$R = \frac{\mu No e^{-\mu x} E}{2} \text{ (for } P^{32}\text{)}$$

Substituting above data:

$$R = \frac{9.5 No e^{-(9.5)(0.007)} .69}{2}$$

$$= 7.0\ C \text{ reps/hr}$$

$$\text{Let } C = 77\ \mu c/cm^2$$

$$\text{Then } R = 7.0 \times 77$$

$$= 539 \text{ reps/hr at 7 mg/cm}^2\ (P^{32})$$

B. Experimentally:

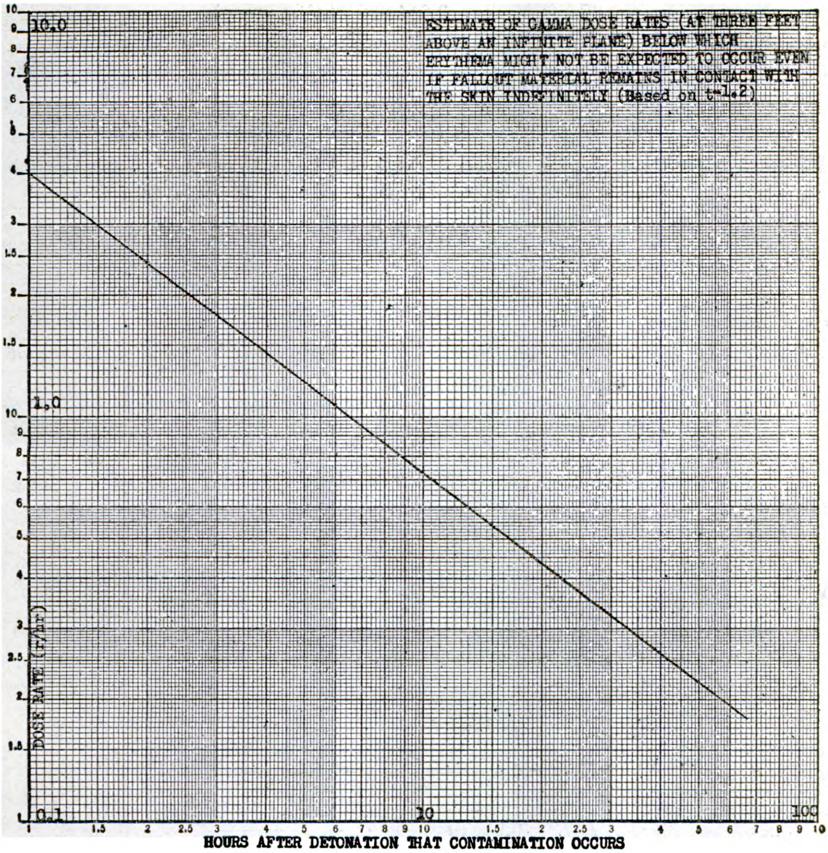
$$R = 457\ e^{-(9.5)(0.007)}$$

$$= 427 \text{ reps/hr at 7 mg/cm}^2\ (P^{32})$$

The two above approaches are within 26 percent of each other. If one extrapolates the experimental data from a source of 9.6 mg/cm² to a thin source (for comparative purposes) the two methods are within 20 percent.

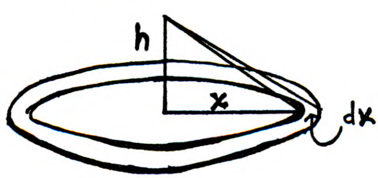
[1] *Effects of External Beta Radiation.* Zirkle, Raymond E. McGraw-Hill Book Co. 1951.

APPENDIX C (a)



APPENDIX D. *Calculations Gamma Dose Rate From a Field 6 Inches in Radius and Center of Chamber 4 Inches Above Surface*

Dose rate of gamma from a point source:



$r \cong 6CE$ where: r = r/hr
C = activity in curies per square foot
E = average energy of gammas (Mev)

$$D = 6CE\, 2\pi \int_0^x \frac{x\,dx}{h^2+x^2}, \text{ where } D = \text{dose rate in r/hr}$$

$$D = 18.8\, CE \ln \left[\frac{h^2+x^2}{h^2}\right]$$

Example:

Let: $x=1/2$ foot
$C=40\mu c/cm^2$ or 3.6×10^{-2} c/ft² (gamma)
$E=0.7$ Mev
$h=1/3$ foot

$$D=(18.8)(3.6\times 10^{-2})(0.7)\ln\left[\frac{(1/3)^2+(1/2)^2}{(1/3)^2}\right]$$
$$=0.56 \text{ r/hr}$$

Comparison Gamma Dose Rates From Infinite Plane at a Height of 3 Feet Above the Ground to Area of 6-Inch Radius and Height of 4 Inches

Assume: 1 megacurie/mile²
(3.6×10^{-2} c/ft²)

$$\frac{4.1 \text{ r/hr}}{0.56 \text{ r/hr}}=7.3$$

APPENDIX E. *Estimate of Dose Delivered by a Single Particle of Fallout Material*

Assume: a. Point source
b. 0.5 Mev average beta energy
c. $\mu=10$ cm²/gm
d. Rate of decay follows $t^{-1.2}$

The dose delivered at the surface of an imaginary sphere at distance R from a point source.[1]

(1) $$K(R)=\frac{CE\mu}{4\pi R^2}e^{-\mu R}\ \frac{\text{Mev}}{\text{gram}}$$

where: $K(R)$ = dose delivered at the surface of an imaginary sphere at distance R
E = average energy of beta particles
C = total number of disintegrations
μ = mass absorption coefficient

Substituting:

$\mu=10$ cm²/gm
$E=0.5$ Mev

Then: (2) $$K(R)=0.4\,\frac{e^{-10R}}{R^2}\ \frac{\text{Mev}}{\text{gm-disintegration}}$$

or (3.a.) $$K(R)=6.9\times 10^{-6}\,\frac{e^{-10R}}{R^2}\ \frac{\text{millireps}}{\text{disintegration}}$$

or (3.b.) $$K(R)=6.4\times 10^{-6}\,\frac{e^{-10R}}{R^2}\ \frac{\text{millirads}}{\text{disintegration}}$$

NOTE.—Equation (3.a.) is plotted on the attached graph.
For fission products:

(4) $$A_a=A_1 t_a^{-1.2}$$

where: A_a = disintegrations per unit time at time "a" after detonation
A_1 = disintegrations per unit time at one unit of time after detonation

Integrating equation (2),

(5.a.) $$C=5A_1(t_a^{-0.2}-t_b^{-0.2})$$
and (5.b.) $$C=5A_a t_a^{1.2}(t_a^{-0.2}-t_b^{-0.2})$$

where: C = total number of disintegrations from time "a" to "b"
t_a = time after detonation
t_b = later time after detonation.

When t_b is infinite,

(6) $$C_\infty=5A_t t.$$

By the use of equations (3.a.) or (3.b.) and (5.b.) one may compute an estimated dose at the surface of an imaginary sphere.

Of course, the problem is the determination of "t_a" and "t_b", i. e., how long after detonation will a radioactive particle be deposited and how long will the particle remain in place. The first time (t_a) is much easier to estimate than the later (t_b).

Radius of Imaginary Sphere in Centimeters

APPENDIX F. ESTIMATE OF BETA DOSES FROM A SINGLE PARTICLE ON THE SKIN (POSSIBLE PRODUCTION OF RECOGNIZABLE ERYTHEMA)

Let: $t_a=3$ hours (time particle is deposited on skin)
$t_b=27$ hours (time particle is removed)

Assume: 1500 reps=total dose required in one day to produce recognizable erythema
0.1 cm=radius of imaginary sphere within which cells must receive 2000 reps or larger.

According to appendix E, 2.5×10^{-7} reps/disintegration is delivered to surface of imaginary sphere 0.1 centimeter in radius.

$$\frac{1.5\times10^{3}}{2.5\times10^{-7}}=6\times10^{9} \text{ disintegrations required}$$

$$C=5A_a t_a^{1.2}[t_a^{-1.2}-t_b^{-0.2}]$$

$$6\times10^{9}=5A_a 3^{1.2}[3^{-0.2}-27^{-0.2}]$$

$$A_a=1.14\times10^{9} \text{ d/hr}$$

or about 8.6 μc at $H+3$ hours.

Of course, the radius of the imaginary sphere selected will materially affect the calculations. For example, a radius of 0.2 cm would require a particle of about 96 microcuries at $H+3$ hours to give the same dose.

APPENDIX G. ESTIMATE OF GAMMA DOSE RATE AT FOUR INCHES FROM A SINGLE PARTICLE OF FALLOUT MATERIAL

Assume: a. The average gamma energy of fission products may be compared with radium; that the average energy of fission products is 0.7 Mev; that the average energy from radium daughters is 0.8 Mev with 2.3 photon emissions per disintegration or that the average energy per disintegration is 2.6 times greater than per disintegration of fission products.
b. A particle of 150 microcuries of beta activity or 75 microcuries of gamma activity. (See appendix H.)

$$I=\frac{8.4 \text{ mg (mc)}}{d^2} \text{ for radium through 0.5 mm of platinum.}$$

where: I=gamma dose rate (r/hr)
d=centimeters

Let: $mc=7.5\times10^{-2}$
$d=10$ cm

$$I=\frac{(8.4)(7.5\times10^{-2})}{10^2}$$

=6.3 mr/hr gamma dose rate at 4 inches (for radium)

$$\frac{6.3}{2.6}\cong 2.4 \text{ mr/hr for fission products}$$

APPENDIX H. *Data and Calculations on Doses From Single Particles of Ruthenium and of Fallout Material*

A. Comparison of beta energies from Ru^{103} and Ru^{106} mixture to that from fission products.

Ru^{103} 0.3 Mev beta (T=42d.)
Ru^{106} ~0.03 Mev beta (T=1.0y.)
Rh^{106} 3.55 Mev beta (T=30s.)

Assume: Ru^{103}/Ru^{106} ratio of 0.75 [1]

[1] All of the basic data contained herein on ruthenium is contained in HW-33068. A status report. Sept. 15, 1954.

To estimate a mean average energy of betas from mixture:

Parts	Isotopes	Maximum energy beta	Weighted maximum energy betas
1.0	Ru^{103}	0.35	0.35
1.33	Ru^{106}	0.04	0.05
1.33	Ru^{106}	[1] 3.35	4.45
Total			4.85

[1] Average.

$$\frac{4.85}{3.66} \cong 1.3$$

Average energy ~0.43 or roughly equivalent to that assumed for fission products.

(Of course, the average energy of the betas is not the sole consideration. The spectral distribution of the betas from Rh^{106} probably is quite different from that of fission products, thus affecting the depth dose curve.)

B. Data on doses and effects from single particles of Ru^{103} and Ru^{106}:

	a	b
1. Size of particle	40 μ	120 μ.
Activity of particle	1.1 μc	11 μc.
Dose rate to 7 mg/cm²	6,600 rads/hr	27,500 rads/hr.
Time dose delivered	~6 days	~6 days.

2. Survey dose rate (mrads/hr)[1]	Total skin dose (rads)[2]	Effects
400	~500,000	None visible.
750	~900,000	Reddening.
2,500	~2,000,000	Desquamation.
11,000	~6,000,000	Tissue destruction.
21,000	~7,000,000	Tissue destruction—2 cm across. 8 mm deep.

[1] 90 mrads/hr≅1 μc.
[2] "Total dose refers to the hot spot directly below the particle, and is valid only as to order of magnitude."

C. $\frac{750}{90} \cong 8.3$ μc estimated activity of particle producing reddening effect in about 144 hours. The estimated size is 100 microns.

D. (8.3) (144) = 1200 μc total activity accounted for in the 144 hours that the dose was delivered. (Assuming constant activity during the 144 hours.)

E. What specific activity of a particle of fallout would be required to deliver the same dose in the same length of time?

The answer to this question depends upon the time after detonation that the particle comes in contact with the skin. Assuming this time to be H+3 hours, the specific activity would have to be about 150 μc for the same size particle.

Since the particle may be washed off before 6 days have expired, one may consider the problem another way. What must be the specific activity of a particle at H+3 hours to deliver this dose in the next 24 hours?

According to Strandgvist (p. 6), only about 70 percent of a 6-day dose need be delivered in one day to produce the same effect (erythema). Accepting this, then a particle with about the same activity (160 μc) at H+3 hours would be sufficient to deliver an erythema dose in 1 day.

F. The following data are reported for single particles collected during Upshot-Knothole and Tumbler-Snapper.

Size of particle (μ)	Activity extrapolated to H+3 hours (μc)	Distance from ground zero (miles)
[1]	1,000	45
[1]	200	130
1,626 x 924	900	10
919	480	11
723	350	14.7
714	400	10
555	140	14.7
387	250	14.7
234	47	14.7
115	5.2	95
81	3.0	14.7
20	.5	

[1] Data from estimations based on radioautograph methods.

It is not intended here to imply these are the maximum specific activities per particle that existed or could exist. The data at 14.7 miles are reported to show the wide range of specific activity that may occur at one locality.

Appendix I. Estimation of Ratio of Surface Beta Dose Rate to Gamma Dose Rate at 4 Inches from an Object 2 Inches in Radius

One may assume a ratio of beta dose rate (at 7 mg/cm^2 depth of skin) to gamma dose rate (3 feet above the ground) of 125/1. If a contaminated object of say 2-inch radius were removed (or shielded) from a general radiation field the gamma dose rate at 4 inches from the surface might be some 40 times less than from an infinite plane with the same degree of contamination (appendix D), while the beta dose rate might remain almost the same value if the object is in contact with the skin. Thus, the beta-to-gamma dose rates measured under these conditions might be 5,000–1. For other than a plane surface, the gamma dose rates might be higher, thus reducing this ratio.

APPENDIX K. METHOD USED IN ESTIMATING DOSES TO THE LUNGS FROM INHALATION OF FALLOUT MATERIAL

Assumptions

The following assumptions are made in estimating radiation doses to the lungs.

A. Twenty percent of the inhaled activity is deposited.

B. There will be no elimination of particles during their radioactive lifetimes. There is uncertainty as to the biological half life of particles in the lungs. In those communities showing the highest concentrations of fallout, the peak of airborne material (which accounted for the greatest percentage of total fallout) occurred only a few hours after detonation. If one assumes a radiological decay according to $t^{-1.2}$ and a biological half life of say 30 days, the omission of biological half life would not affect seriously the computed total dose.

C. All of the activity is associated with particles in the respirable range of sizes. Past data from cascade impactors indicate that about 90 percent of the activity is associated with particles 5 microns or less in the communities surrounding the Nevada test site.

D. The lungs are uniformly irradiated.

E. The weight of the lungs is 900 grams.

F. An individual inhales 20 cubic meters per 24 hours.

G. The average beta energy is 0.5 Mev.

H. The gamma dose is negligible compared to the beta dose.

Data at St. George, Utah

(Short time) 0505 (I)	Duration (II)	Approximate midpoint after detonation III	$^{1}\mu c/M$ (IV)	μc Inhaled (col. II times col. IV times 0.834) (V)	μc Retained (col. V times 0.2) (VI)
	Hours	*Hours*			
0610 to 1130	4.8	3	4.17	15.9	3.0
1130 to 1445	3.2	8	2.38	6.3	1.26
1445 to 1845	4.0	11.5	6.3×10^{-1}	2.1	0.42
1845 to 2300	4.2	15.6	4.4×10^{-2}	0.15	0.03
2300 to 0635	7.5	21.5	1.4×10^{-2}	0.09	0.02
[1] 0635 to 1835	12.0	31.5	1.4×10^{-2}	0.14	0.03

[1] Assumed.

Sample calculations

$$D=5At_a^{1.2}[t_a^{-0.2}-t_b^{-0.2}]$$

Let: $t_a=3$ hours
$t_b=2184$ hours (13 weeks)
$A=3\ \mu c$

$$D=(5)(3\times2.22\times10^{6}\times60)(3)^{1.2}[3^{-0.2}-2184^{-0.2}]$$

$=4.4\times10^{9}$ disintegrations from 3d hour to 13th week.

Assume: $E_{avg.}=0.5$ Mev

$$(4.4\times10^{9})(0.5)(1.6\times10^{-6})\left(\frac{1}{900}\right)\left(\frac{1}{39}\right)=4.2\times10^{-2}\text{ reps}$$

$$=42\text{ mreps}$$

Total lung dose for 13 weeks: ~130 mreps.

APPENDIX L. ESTIMATE OF DOSE AT SURFACE OF IMAGINARY SPHERE 1 MILLIMETER IN RADIUS

Assume: Average activity for 30 minutes is 0.5 μc at H+3 to H+3½ hours. (See reference appendix H.)

Then: $0.5\times 2.2\times 10^6\times 30=3.3\times 10^7$ disintegrations/30 minutes.

At surface of imaginary sphere 1.0 mm. in radius the dose rate from a point source is

$$2.52\times 10^{-4}\frac{\text{mreps}}{\text{disintegration}} \text{ (See appendix E.)}$$

$$(3.3\times 10^7(\ (2.52\times 10^{-4})=8.3\times 10^3 \text{ mreps/30 min.}$$
$$\cong 8 \text{ reps/30 min.}$$

For particles of higher specific activity, the dose would be correspondingly higher, of course.

APPENDIX M

UNITED STATES ATOMIC ENERGY COMMISSION,
Washington D. C., August 2, 1957.

Hon. CHET HOLIFIELD,
Chairman, Special Subcommittee on Radiation,
Joint Committee on Atomic Energy,
Capitol Building, Senate Post Office, Washington, D. C.

DEAR MR. HOLIFIELD: As a part of the written record of The Nature of Radioactive Fallout and Its Effects on Man, there is being reproduced a document Discussion of Radiological Safety Criteria and Procedures for Public Protection at the Nevada Test Site written by me some time ago. I would greatly appreciate it if a footnote (attached) were added to this document.

Also enclosed is a copy of the revised radiological safety criteria (April 1957) that are currently being used. I would like to suggest respectfully that these revised criteria also be printed so that the reader may have the benefit of our latest thinking on these matters.

Sincerely yours,

GORDON M. DUNNING,
Health Physicist, Division of Biology and Medicine.

Radiological Safety Criteria During Nuclear Weapons Testing at the Nevada Test Site

(April 1957)

INTRODUCTION

The criteria and procedures set forth in the following paragraphs were established after full consideration for protecting the health and welfare of the public, both in terms of radiological exposure as well as possible hazards, hardships or inconveniences resulting from disruption of normal activities. Criteria are established as guides for the Test Organization in determining whether any special actions should be taken to protect the public.

These criteria are not established with the expectation that the coming tests at the Nevada Test Site actually will result in radiation levels which will be greater than heretofore. Rather, they formalize past criteria to give even clearer guides for protecting the public. With improved methods of predicting fallout and with the use of balloons and higher towers for detonating the nuclear devices, it is expected that fallout in populated areas from future tests at the Nevada Test Site will be less than the highest amounts which have occurred in the past.

Two basic assumptions are made in this report:

(*a*) It is the responsibility of the Division of Biology and Medicine to establish such criteria for the Atomic Energy Commission as deemed necessary to protect the health and welfare of the general populace from consequences of weapons tests conducted at the Nevada Test Site.

(*b*) The operational procedures adopted for meeting these criteria shall be the responsibility of the Test Manager, as directed by the Division of Military Application, with the technical guidance of the Division of Biology and Medicine.

The following criteria do not apply to domestic or wild animals since levels of radiation which would be significant to them would have to be higher than those specified herein.

Section I. Evacuation

BACKGROUND

The decision to evacuate a community is critical for two principal reasons. One, presumably there might be a health hazard if the personnel were allowed to remain. Two, there is always an element of danger and/or hardship to personnel involved in such an emergency measure.

It is recognized that extenuating circumstances may accompany any situation where conditions indicate evacuation as a mode of action. The size of the community, areas and accommodations available for the evacuees, weather conditions, means of transportation and routes of evacuation, disposition of ambulance cases, protection of the property left behind, and many other factors may enter into the decision relative to evacuation. Further, it is recognized that under certain conditions, the evacuation of a community might prove not only rather ineffectual but could result in more radiation exposure than if the population remained in place unless the situation be adequately evaluated. A blanket evaluation cannot be made in advance; each situation can be unique. The following criteria therefore are suggested as guides in assessing the possible radiological hazards; the final decision must be made on the basis of all relevant factors known at the time. They are intended to apply principally to relatively large populations since small groups may be evacuated without equivalent potential hazards.

Owing to the necessity of making early measurements and decisions, it is to be expected that dose-rate readings, taken with survey meters, will be the available evidence at the times of concern. This necessitates making rough approximations in advance of the effects of weathering and of shielding from normal housing, in reducing the radiation exposure. The variable nature of these two parameters makes impossible the establishment of a precise rule covering all situations. Therefore, the following may be used in making conservative estimates of these effects:

(*a*) For weathering—the measured gamma dose rates at three feet above the ground be assumed to decay according to $(t)^{-1.2}$ for the first week after a detonation, $(t)^{-1.3}$ for the second week, and $(t)^{-1.4}$ thereafter.[1]

(*b*) For shielding—the accumulated dose per day be 25% less than the out-of-doors dose.[2]

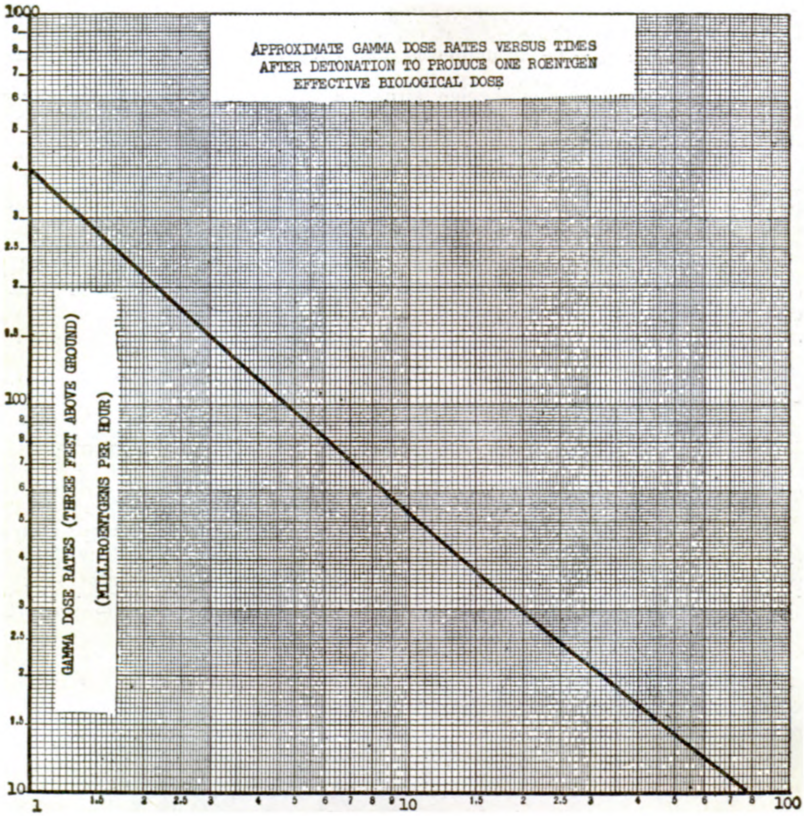
In the case of a truly emergency situation where potential hazards may exist either from the fallout or from mass evacuation of large populations, it would seem proper than due consideration be given to the biological repair process that takes place with radiation doses distributed in time (recognizing that such effects from radiation as genetic changes and life shortening may not be time dependent). The estimates for biological repair for man are quite uncertain so a conservative value is used here of a half-time of repair of about four weeks.

Graph I incorporates the above factors of weathering, shielding, and biological repair into a single curve. This graph may be linearly extrapolated to other dose rate readings. For example, if fallout occurs three hours after detonation and the dose rate is 10 r per hour, then about 67 r (effective biological dose) may be accumulated, i. e., $\frac{10}{0.15}\times 1.0=67$

[1] This concept was suggested after analyzing data from both the Nevada Test Site and the Eniwetok Proving Ground and is intended to give generalized estimates to cover a wide variety of situations. It is recognized that with the smaller fallout patterns and with the sandy soils around the Nevada Test Site, the effective decay constants may be greater than these. An expanded monitoring program will be in operation during Operation Flumbbob (1957 Series) for the collection of pertinent data to allow better estimates of effective rates and of the efforts of shielding provided by buildings.

[2] This is based on an average 12 hours per day stay in a frame house having an attenuation factor of two. It is recognized that some individuals will be in buildings having higher attenuation factors, and for longer periods of time. On the other hand, this is generally an area where people may live an appreciable amount of time out of doors and where windows and doors are left open, so the fallout material may enter the buildings. Possible revision of these estimates will await results from the expanded monitoring program during Operation Plumbbob.

GRAPH I



CRITERIA I

Effective Biological Doses may be calculated according to Graph I.

Table I may be used in evaluating the feasibility of evacuating relatively large populations.

TABLE I.—*Radiological criteria for evaluating feasibility of evacuation*

Effective biological dose:	Minimum effective biological dose that must be saved by act of evacuation (otherwise evacuation will not be indicated):
Up to 30 roentgens	(No evacuation indicated.)
30 to 50 roentgens	15 roentgens.
50 roentgens and higher	(Evacuation indicated without regard to quality of dose that might be saved, providing adequate shelters are not available and the estimated hazards concomitant with evacuation are acceptable.)

Section II. Personnel Remaining Indoors

BACKGROUND

By remaining indoors (*a*) the gamma exposure will be reduced, and (*b*) there is less possibility that the fallout material will come into contact with the skin. (Beta burns have occurred in the past only when the fallout material has remained in direct contact with the skin.) To prevent or greatly reduce this latter effect, it is highly desirable to make decisions before or very shortly after the start of the fallout. Likewise, partial shielding at these early times will be of optimum benefit due to the relatively high gamma dose rates. Thus, the decisions must be based on predicted fallout in an area, or on dose-rate readings from field monitors' reports.

These predictions are of course subject to varying degrees of uncertainly so that personnel may be asked to remain indoors unnecessarily. On the other hand decisions and action must be taken relatively quickly if optimum benefits are to be derived and remaining indoors until the radiological information is more accurately evaluated probably represents one of the easiest and effective ways of meeting an emergency situation.

Due to uncertainties in our knowledge, and recognizing the usual unequal distribution of fallout, it has not been possible to establish precisely the amount of fallout in an area that could produce beta burns. The Marshallese experience showed such effects for those people exposed to 175 r and 69 r whole body gamma radiation, but none for those individuals on the Island of Utirik (370 miles from ground Zero) receiving 14 roentgens. Whether these results would hold true for other situations is not known, i. e., different particle size distribution, different type skin, etc. At one location, Riverside Cabins, Nevada, about 15 people were in an area receiving fallout in an amount equivalent to infinity dose of 15 roentgens, with no known cases of beta burns, although it is not known if anyone was out-of-doors during the time of fallout. Until more is learned of this phenomenon, it would appear advisable to remain out of the direct fallout when the amount would be such as to produce about 10 roentgens gamma infinity dose as measured at three feet above the ground. In the event personnel are out of doors during the time of this amount of fallout, the possibility of beta burns could be greatly reduced by the simple expedient of changing clothing and of bathing.

If people were not asked to remain indoors during the period of highest dose rates in an area where the infinity dose was 10 roentgens or more, their actual exposure might be in excess of 3.9 roentgens of wholebody gamma. This would not necessarily be hazardous but would exceed the established criteria for Plumbbob (Criteria VI).

CRITERIA II

When the gamma dose rate reading as measured by a survey meter held three feet above the ground reaches the values given in Graph II at the times indicated, it is recommended that personnel be requested to remain indoors with windows and doors closed. Release from this restrictive action should be made on the basis of further evaluation of the radiological conditions.

In the event that there be convincing evidence that the radiation levels given in the graph will be reached, it is recommended that personnel be requested to remain indoors BEFORE fallout occurs or before the radiation levels equal those in Graph II. Release from this restrictive action should be made on the basis of further evaluation of the radiological conditions.

It is recommended that people who had been out of doors during fallout of the above magnitude or greater be advised to change clothing and to bathe. The clothing may be cleaned by normal means. While bathing, special attention should be paid to the hair and any exposed parts of the body.

In the event that the monitoring takes place AFTER the fallout has occurred, and extrapolation of the dose rate readings equals or exceeds those in Graph II at the estimated time of fallout, then it is recommended that the same advice be given as in the preceding paragraph.

Section III. Decontamination of Personnel

BACKGROUND

The principal purposes for decontaminating personnel are to reduce the potential beta doses to the skin, and to a lesser degree reduce the external gamma exposure. The discussion on beta doses in Section II is applicable here. In addition, there is much unknown about monitoring methods for personnel contamination. The following criteria were previously developed on the basis of measuring the gamma radiations (and then extrapolating to the accompanying beta radiations) with existing instruments. Recently new field instruments have been developed for direct beta measurement, but there remains considerably more work necessary to calibrate them in terms of beta dose rates to the body. Until this is accomplished, the past criteria may be used.

CRITERIA III

Where it is not possible to monitor personnel outside of a general radiation field, it is recommended that an estimate be made of the degree of personnel contamination by determining the location of the individual at the time of fallout. In the event there is uncertainty as to the validity of such an estimate, the assumption will be made that the individual was out-of-doors during the time of fallout. In those areas where the infinity gamma dose equals or exceeds 10 roentgens, it is recommended that the individual be advised to bathe and to change clothing.

For personnel being monitored outside the general radiation field where personnel contamination exists over relatively large areas of the EXPOSED body (one-half square foot or more):

When the reading of a survey instrument held with the center of the probe or center of the ionization chamber four inches from the center of the contaminated area, equals or exceeds the values given in Graph III it is recommended that personnel be advised to bathe and to change clothing.

For personnel being monitored outside the general radiation field, where personal contamination exists over relatively small areas of the EXPOSED body (less than one-half a square foot):

The recommended maximum values are one-half those given in Graph III. Monitoring of the head, arms, hands, lower legs, and feet will be considered as coming under this category. Washing may be limited only to the contaminated parts, and also a change of clothing may not be indicated, unless the radiation levels exceeds those stated below concerning monitoring of exterior surfaces of clothing.

For personnel being monitored outside the general radiation field, and the contamination exists over only spots of EXPOSED body (about the size of a half-dollar or less):

The recommended maximum values are one-fifth those given in Graph III.

Washing may be limited only to the contaminated parts, and also a change of clothing may not be indicated unless the radiation levels exceed those stated below concerning monitoring of exterior surfaces of clothing.

For personnel being monitored outside the general radiation field and the contamination exists over any size area on the exterior surface only of the clothing:

The recommended values under these conditions are twice those given in Graph III. The first recommended action shall be to resort to such simple acts as brushing off the clothing. If this action does not reduce the radiation levels to twice those given in Graph III or less, then personnel should be advised to change clothing and to bathe.

When the general contamination of a community is of the degree to produce an estimated maximum theoretical infinity gamma dose of 20 roentgens or greater, personnel who have been out-of-doors at any time during the first two days and generally moving around in the area (as apposed to such an act as walking only between a building and a vehicle) should be advised to brush off the footwear (outdoors), to bathe and to change clothing as soon as possible after the final return indoors each day. In addition personnel who go out-of-doors for any length of time during the first two days after such a fallout should be advised to wash their hands at least after the final return indoors each day, and more frequently, if possible.

SECTION IV. DECONTAMINATION OF MOTOR VEHICLES

BACKGROUND

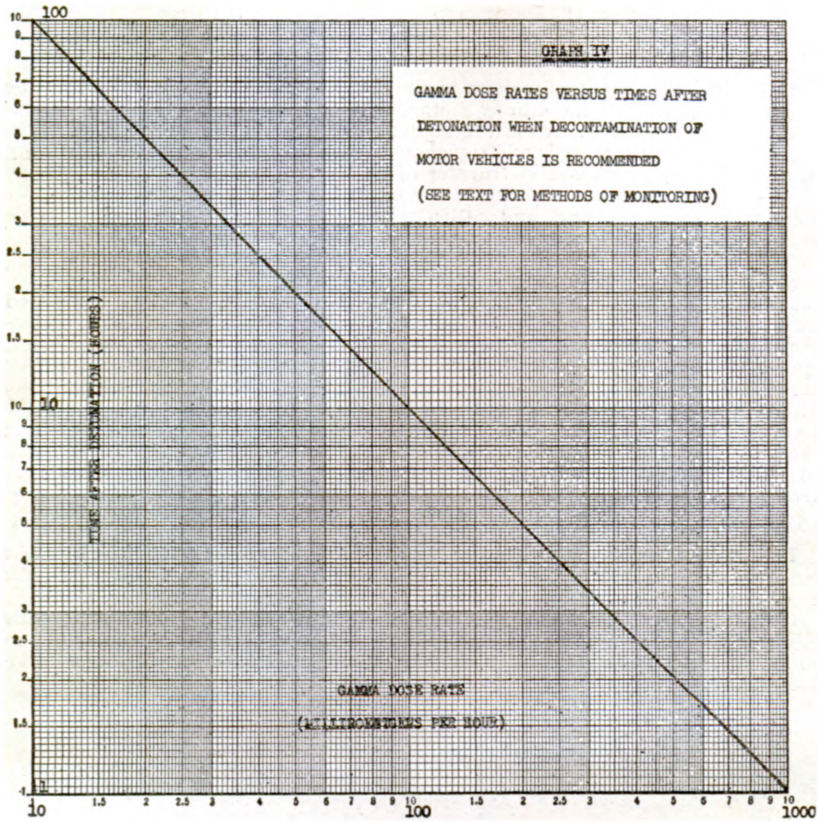
The principal purposes for decontaminating motor vehicles are to reduce the potential beta doses to the skin by contact with the vehicle, and to reduce the external gamma exposure. All of the uncertainties inherent in personnel monitoring are applicable here plus additional ones, such as estimates of the probability of contact and the amount of transfer of radioactive material from the vehicle to the skin. The following criteria for monitoring motor vehicles (Graph IV) were previously developed, and until the new beta measuring instruments (see Section III) are calibrated, will continue to be recommended.

One method of avoiding or significantly reducing vehicle contamination is to prevent their being in an area during the time of actual fallout. It is possible that fallout across a highway may be higher than that permitted for populated areas. When such a condition is predicted, it would be advisable to hold vehicular traffic until after the fallout had essentially ceased. Past experience has shown that very significantly less vehicle contamination occurs when it passes through an area afterwards compared to being present during the fallout time, although appreciable amounts can still be picked up on the tires and under the fenders. Obviously, there is not a precise value that may be given, but it is recommended that if the amount of fallout across a main highway is predicted to be in an amount equivalent to 10 roentgens or greater infinity dose, that traffic be temporarily halted until the fallout has essentially ceased.

CRITERIA IV

It is recommended that when the predicted fallout across a main highway be equivalent to 10 roentgens or greater infinity gamma dose, vehicles be held until the fallout has essentially ceased

Graph IV may be used in determining the advisability of decontaminating motor vehicles. The survey instrument should be held with the center of the probe or center of the ionization chamber four inches from any readily accessible surface.



SECTION V. CONTAMINATION OF WATER, AIR AND FOODSTUFFS

BACKGROUND

In any area where the theoretical gamma infinity dose exceeds 10 roentgens, adequate sampling of the water, air, and foodstuffs should be made to ascertain the conditions of possible contamination, if for no other reasons than as precautionary and documentary measures. Based on past data, however, *it is not* expected that under those conditions of fallout where the radiation levels are below those stipulated for possible evacuation, that the degree of contamination would be a health hazard. Nor is it implied here that any level above this does constitute a serious contamination of water, air, or foodstuffs. One good point of reference is the Marshallese experience where the whole-body gamma exposure was 175 roentgens yet the internal deposition from ingestion and inhalation was relatively small. In the event of a relatively heavy fallout, but less than one calling for evacuation, a common sense rule would be to wash exposed foods, such as leafy vegetables, since this is the most probable mode of intake of activity.

CRITERIA V

Monitoring of air, fod and water should be made as soon as possible in areas where the infinity dose equals or exceeds 10 roentgens. There need be no restrictive action imposed on food and water intake in areas where the fallout is less than that calling for evacuation. Washing off of such exposed foods as leafy vegetables may be advised when such action seems desirable.

SECTION VI. ROUTINE RADIATION EXPOSURES

BACKGROUND

The Atomic Energy Commission has adopted, as an operational guide, 3.9 roentgens whole body external gamma radiation for off-site exposure resulting from Operation Plumbbob.

The discussion in Section I on effects of weathering and shielding on determining the actual radiation exposure is applicable here. However, the factor of biological repair is not considered for routine exposures. This factor bears on somatic effects and may justifiably be considered in emergency situations when it is necessary to weigh the relative hazards from radiation versus mass evacuation. However, for routine exposures, the actual (estimated) roentgen dose should be used. To distinguish from the Effective Biological Dose and the Infinity Dose, this exposure will be expressed as the Estimated Dose.

Graph V incorporates the assumed effects of weathering and of shielding according to the discussion in Section I. The graph may be linearly extrapolated to other dose-rate readings. For example, if fallout occurs three hours after detonation and the dose rate is 360 milli-roentgens per hour, then about three roentgens (estimated dose) may be accumulated, i. e., $\frac{360}{120}\times 1=3$.

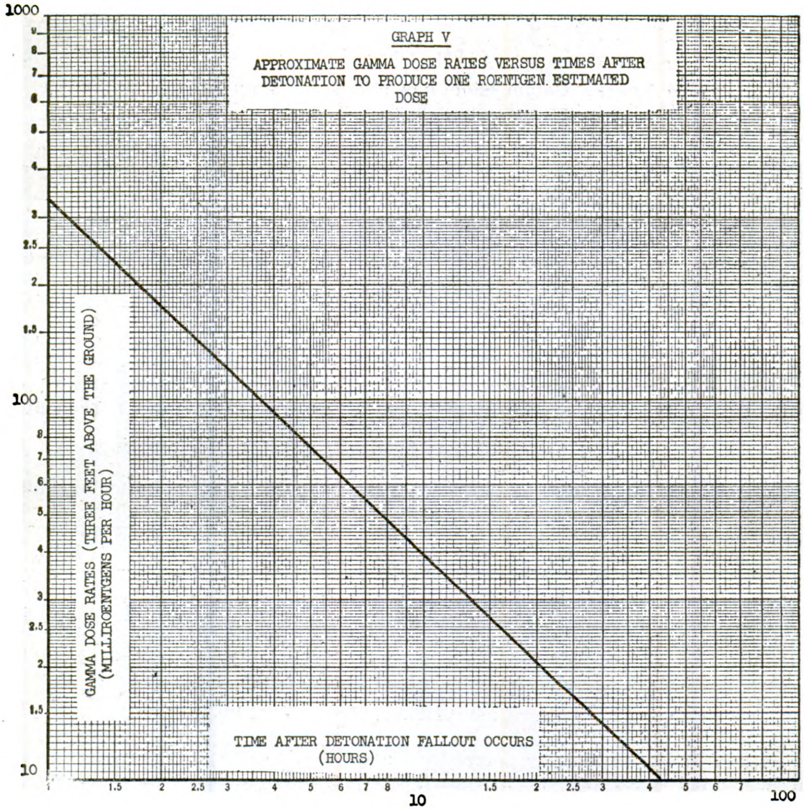
As discussed in Section I, the estimates of the effects of weathering and of shielding may be conservative for areas around the Nevada Test Site. A range of radiation doses is to be expected for these people since they will not all be living under identical conditions. The radation doses estimated by the present method is expected to fall within and toward the upper end of such a range. The information obtained from the expanded radiological monitoring program for Operation Plumbbob, should yield refinements in the method of estimating the radiation exposures.

In those cases where film badges are worn properly by personnel, the values recorded may be accepted as the Estimated Dose.

CRITERIA VI

Estimated Doses may be determined according to Graph V. In those cases where film badges are worn properly by personnel, the values recorded may be accepted as the Estimated Dose.

The whole-body gamma Estimated Dose for off-site populations should not exceed 3.9 roentgens resulting from Operation Plumbbob. This total dose may result from a single exposure or series of exposures.



Representative HOLIFIELD. This afternoon we will have Dr. Forrest Western, Division of Biology and Medicine, Atomic Energy Commission; Dr. Lyle Alexander, Department of Agriculture; and Dr. Roger Revelle, Scripps Institute of Oceanography, as witnesses.

We will meet in the Senate caucus room, room 318, at 2 p. m.

Before we recess, I have several statements to insert in the record at this point. The first is a statement of the United States Naval Radiological Defense Laboratory concerning the prediction, measurement and analysis of fallout and radiological countermeasures. Next a statement by LeRoy H. Clem, of Headquarters, Air Weather Service, United States Air Force. The third is a statement by Col. B. G. Holzman, and Col. Norair M. Lulejian, of the Air Force Research and Development Command, fourth is a statement by Dr. Donald M. Swingle, of the Army Signal Corps, Evans, South Carolina Laboratory, and finally a presentation submitted by James G. Terrill, Jr., Chief, Radiological Health Program, Public Health Service.

STATEMENT OF UNITED STATES NAVAL RADIOLOGICAL DEFENSE LABORATORY

PREDICTION OF FALLOUT

It was realized after the early weapons test operations that there existed a requirement for predicting the then little understood phenomenon of fallout. NRDL made the first studies on this subject by employing scaling techniques (1, 2, 3) similar to the approach used in the determination of blast and thermal

effects for weapons over a wide range of yields. Such scaling of radiological phenomena resulted in satisfactory results when compared to the meager experimentally determined field data (4). As more effects data became available from subsequent weapons test operations (5, 6, 7, 8) the limitations of a straightforward scaling technique were observed and the increasing dependence of the fallout on the dynamical parameters involved, such as the meteorological variables, became apparent. This led to the development of a physical model that would hopefully explain the mechanism of fallout such that given the required input parameters a knowledge of the fallout phenomenology for any type of nuclear detonation could be predicted (2, 9, 10). This model development was initiated by concentrating the effort on surface land detonations. Very little factual data were available for construction of such a model. However, it was realized that this approach offered the most positive chance of success and consequently theoretical assumptions regarding the model input parameters would have to be made. This model then defined the cloud source and associated parameters such as particle size distribution and relation of activity to particle size. A mechanism theory based on the particle settling rates and the effect of the winds aloft in determining the trajectories of these particles was established. A mathematical technique of summing the deposited activity on the earth's surface was developed such that the fallout pattern would then be established.

Because of the many initial assumptions made a great deal of effort was taken in subsequent nuclear weapons test operations to obtain refinements of these parameters by measurement (2). This work included detailed physical, chemical and radiochemical analyses of fallout particles, time dependent studies on the fallout such as time of arrival as a function of distance, rate of arrival, and time to peak activity. Activity levels as a function of distance were made (5, 6, 7). Rockets were employed to establish the radioactivity profiles within the mushroom cloud (11). Such experimental data were employed in the refinement of the physical model as well as were detailed studies of the effect of time and space variation of the winds aloft on the trajectories of the fallout particles. This data greatly improved the ability of the model to predict the fallout and continuing refinements are being made. The use of a physical model for understanding and predicting fallout appears justified (12).

A fallout forecasting technique has been developed to satisfy the immediate needs of the military. This technique employs many of the model parameters established. However it was designed for operational use and predicts only the perimeter of the fallout pattern and the radiological axis of the area or "hot line" (13, 14). It is a rapid system that was tested at Operation Redwing and proved very satisfactory for both surface land and surface water detonations. The details of this technique are described in the enclosed NRDL Technical Reports TR-127 and TR-139.

There has not been developed a satisfactory physical model for underwater or underground detonations to date. For these cases and environmental conditions other than surface or near surface burst the use of scaling techniques holds the most promise. However it is not inconceivable that the mechanism of such detonations will be understood and subsequent models developed.

The accuracy of prediction of fallout is very dependent on the quality of the meteorological data available. With precise meteorological data the area of fallout and direction of the axis of the pattern can be excellently forecast. The quantitative prediction of radiation levels at any point within the fallout area is much more difficult to predict.

It is considered essential in order to insure the application of fallout prediction technique and radiological hazard assessment to a wide variety of detonation conditions that the basic mechanisms responsible for formation of fallout, movement of fallout material in atomic clouds, its dispersal by meteorological forces and return to the earth's surface be thoroughly understood. Only a beginning to develop such an organized set of scientific data has been made.

Measurement of Fallout

It has been the overall objective of the fallout measurements made by NRDL at the Nevada test site (3, 9, 12) and the Eniwetok Proving Grounds (1, 5, 6), to obtain those data which would allow prediction techniques to be tested and assessment methods developed for the radiological situations resulting from a wide range of nuclear detonation conditions (8).

Since fallout predictions result in the construction of gamma intensity contours, one group of measurements has featured the collection of experimental data for such contours. Direct measurement of the gamma ionization rate at a large number of points in the fallout area with a hand survey meter is the simplest and in many ways the most satisfactory method of obtaining this type of information (2, 4). When the fallout has been deposited on a solid surface, as in Nevada, surveys of this type have generally been used and further supplemented with measurements on instruments calibrated in terms of ionization of the activities of samples collected at certain locations for the primary purpose of physical, chemical, and radiochemical studies. When the fallout has been deposited on a water surface, as in the Pacific, certain other measurements are required for the interpretation of survey results. Because of the way in which the fallout material settles and disperses in the water, it has been necessary to measure its distribution to the total depth of mixing at each point of measurement before the total fallout deposited at that point could be computed. This has been accomplished in part by the use of a radiation sensitive probe which could be lowered to various depths, and in part by measuring the activities of samples collected at various depths. Both procedures have required critical instrument calibrations and theoretical work involving a number of assumptions, however, and it is probable that the results are much less accurate than those for the land surface case. In general, the measurements of this kind made by NRDL have shown that areas of the order of tens of square miles are subjected at early times to ionization intensities greater than 5 r/hr. by events in the low KT range and areas of the order of thousands of square miles to ionization intensities greater than 5 r/hr. by events in the MT range. Levels of several thousand

r/hr. at early times for both yield ranges have been measured or inferred, although less than 10 percent of the total affected area was estimated to have experienced these levels. While the probable error for contours from survey ionization rate measurements has been estimated ±20 percent for Nevada KT events, corresponding land equivalent contours for MT events in the Pacific cannot be estimated closer than within a factor of 2 or 3 at the present time.

Another group of measurements has ben directed toward obtaining time dependent data, such as the variation of the gamma field intensity and gamma energy spectrum with time and the distribution of particle sizes deposited with time at a number of locations in the fallout area (10, 12). Such information is needed both to check model theory which yields similar results and to provide a complete description of fallout phenomena. The changing gama radiation field has usually been measured by means of an instrument which recorded increments of ionization dose received at its location from all sources within unit time intervals, while gamma energy spectra have been measured on fallout samples from a known fallout area with an instrument utilizing a crystal detector, a photomultiplier and a pulse height discriminator (7, 12). NRDL results have shown that the gamma radiation field due to fallout outside the area of severe blast damage tends to build up to a maximum in approximately twice the time required for the fallout to arrive, varying from a few minutes near ground zero to 24 hours or more at distances of over 100 miles. The radioactive decay of fission products may be approximately by a straight line of slope—1.2 on a log log plot; however the more general case in which several induced activities are present, and the fission products are fractionated, leads to a complex decay curve. Spectral measurements show the average energy of the fallout gamma radiations to vary from about 0.6 Mev. at 10 hr. to 0.3 Mev. at 360 hr.

The determination of particle size distributions with time has required the development and application of specialized collectors capable of sampling automatically over consecutive time intervals from a few minutes to an hour or more, as well as special methods and instruments for sizing and counting the collected particles. It has been found that particles with diameters between 100 and 300 microns predominate in most collections with larger sizes (2,000–3,000 microns) increasing nearer ground zero and smaller sizes (20–100 microns) increasing farther away from ground zero. In general, data of this kind, being more direct, are more reliable for computing fraction of the bomb in the total fallout than survey results—although several sources of error such as sample bias 11 and radionuclide fractionation, do exist. On the scale utilized above, standard error in fraction calculations might be estimated at about ±25 percent for the gamma energy and emission rate method, as opposed to possibly several hundred percent by the survey method for water surfaces and less than 100 percent for land surfaces.

Extensive physical, chemical, and radiochemical analyses have been performed on the particulate produced by detonations occurring on the sandy Nevada soil and on coral atolls and the ocean surface in the Pacific. The mass of such material as well as the fraction of the bomb deposited per unit area at a number of locations has also been determined by weighing collected samples and performing radiochemical analyses. Since fallout ingestion constitutes a separate hazard from exposure to external fallout radiation, and since countermeasures and recovery procedures depend heavily on knowledge of the various properties of the contaminant, information of this kind is essential for assessment purposes.

NRDL has consistently emphasized measurements of local fallout and characterization of the phenomena associated with it. It has been possible, nevertheless, to estimate the fraction available for worldwide fallout by subtraction of the local fallout from the total produced, and this has been found to be something of the order of 50 percent for both land surface and water surface events. No closer estimate can be given because of the many uncertainties and sources of possible error in the measurements and calculations.

Environmental Aerosol Analysis

The United States Naval Radiological Defense Laboratory (USNRDL) collects and analyzes daily aerosol samples for airborne activity of air passing over the laboratory. Twenty-four-hour air samples have been collected and analyzed daily since January 1950, and is a continuing program at the laboratory. The attached graphs present a summary of the long-lived activity and half-life for these daily aerosol samples. Additional analysis on representative aerosol samples indicated this activity is due to airborne beta-gamma fission products. The appropriate dates of the various United States nuclear weapon tests are indicated.

It is observed from the graphs that in 1950 there was essentially no fission product activity in excess of 10^{-14} $\mu c/cc$. In 1951, the aerosol activity rose during the Ranger and Greenhouse operations but then dropped back to an average of $3x10^{-14}$ $\mu c/cc$. Successive rises and falls of the aerosol activity are noted for the succeeding years. The rises in aerosol activity, fall of 1951, 1953, 1954, 1955, and 1956 were not produced by the United States or United Kingdom nuclear weapon tests. Since December 1955, the aerosol activity has varied between 10^{-13} and 10^{-12} $\mu c/cc$. In other words, the fission product activity background was less than 10^{-14} $\mu c/cc$ in 1950, but is now around $5x10^{-13}$ $\mu c/cc$. The present concentration of airborne fission products is at most one-tenth of the natural radiactive aerosol (radon and thoron) concentration and is one-fifty thousandth of the industrial maximum permissible concentration for continuous exposure to undetermined mixtures of beta-gamma emitters.

NATURAL RADIOACTIVE AEROSOLS

The earth's surface atmosphere normally contains radioactive aerosols produced by the radioactive decay products of uranium and thorium minerals in the earth's crust. The amount of these natural radioactive aerosols varies from 10^{-14} μc/cc. to 10^{-11} μc/cc. as determined by the earth's mineral composition in a particular locale. The unit μc/cc. (microcuries per cubic centimeter) is a measure of the amount of radioactive material per unit volume suspended in the air. 10^{-9} μc/cc. is the present industrial maximum permissible concentration for continuous exposure to undetermined mixtures of beta-gamma emitters.

PROCEDURES

Every air sample contains natural radioactive decay products (mainly radon from the uranium series and thoron from the thorium decay series), and any other radioactive material contamination such as fission products, suspended in the air. In the analysis of the aerosol samples collected at USNRDL, the natural radioactive aerosol products, radon and thoron, are subtracted from the total aerosol activity. The daily aerosol samples are collected at USNRDL by passing 600 cubic meters of air through a 2-inch diameter high efficiency filter paper. The filter paper is then automatically counted for beta-gamma activity with a geiger tube and scaler. The minimum limit of detection on the USNRDL equipment is 10^{-14} μc/cc.

RADIOLOGICAL COUNTERMEASURES

INTRODUCTION

Most of the USNRDL concepts relative to countermeasures against nuclear attack have been previously presented in the hearings before the Subcommittee of the Committee on Government Operations. One part covering our general concepts appears in part 6 of the hearings on Civil Defense for National Survival held at San Francisco and Los Angeles on May 24, 25, 28, 29, and 31, 1956. These concepts were expanded in those portions involving the emergency periods at hearings held on H. R. 2125 at Washington, D. C., on February 5 and 6, 1957.

GENERAL CONCEPTS

The overall objective of radiological defense is to minimize the effects of nuclear attack on operations. Three time phases of defense actions are apparent: emergency phase; operational recovery phase; final recovery phase. The objectives in each phase are respectively: survival; early recovery of essential functions; ultimate recovery of normal functions. In everyday language, these objectives on a national scale are survive, stay in the war, and win the peace. There is a definite interaction between these objectives: actions which can be taken in any one phase will depend on those taken in other phases.

The general concepts on which the time phases and the respective countermeasures which apply to each phase are discussed in references 1, 2, 6, 8, 9, and 13. Our basic conclusions (reference 9) are that shelter is the central countermeasure in the emergency phase and reclamation is the central countermeasure in the operational recovery phase. The central countermeasure for the final recovery phase will probably be some form of exposure control actions; the precise nature of the actions that will be required have not as yet been taken under investigation by NRDL. In addition, reference 9 discusses other countermeasures that can be used to supplement the central countermeasures; these are called peripheral countermeasures. They include such actions as dispersal, evacuation, operational adjustments to regulate exposure to radiation.

These concepts are applicable to the case of large-scale attack with high yield thermonuclear weapons wherein all persons will be subject to effects of the attack and significantly larger areas will be subject to fallout than any other combination of effects. The concepts also apply to attack with small yield weapons in localized areas where a more limited number of people are subjected to the effects of fallout alone. People in these areas must be prepared to achieve the objectives of the defense system.

COUNTERMEASURE APPLICATIONS

Radiological countermeasures are actions that are designed to reduce, eliminate, or control exposure of personnel to radiation from radioactive material. In the emergency and operational recovery phases, the principal radiological

hazard to personnel is that from external gamma radiation. In the final recovery phase (starting several years after attack), the principal hazard is an internal one from continuous ingestion and/or inhalation of long-lived radioactive materials. Because of the long periods of possible exposure of personnel living in a radioactively contaminated environment, countermeasures must be planned as a phased, long-term, continuous, and coordinated system. Concepts and guides for planning such a system are given in references 1, 2, 8, 12, and 13. The overall system planned for a given installation or locality must be based on an analysis of the vulnerability of the target area to attack and must be independent of the condition of attack.

COUNTERMEASURE COMPONENTS

1. Shelters

The optimum requirement for the shielding afforded by a radiological shelter is a reduction in the radiation intensity of the order of 1,000 to 5,000; the use and requirements for shelters are discussed in references 1, 8, 9, 10, 13, 14, and p21. Reference 14 describes a national shelter system consisting of (*a*) simple radiological shelters, (*b*) radiological shelters with fire-storm protection in areas where fire storms could occur, and (*c*) high-performance shelters in densely populated areas to protect against high blast pressures and fire storms as well as against nuclear radiations. Many existing buildings can serve as adequate shelters; others can serve with some modifications.

2. Reclamation

The basic reclamation techniques presently available and tested are (1) manual decontamination of paved areas, building surfaces, ships, and aircraft; (2) earth-moving procedures on open land areas; and (3) automatic washdown on ships. Most of the data on decontamination are from laboratory experiments on sea-water type fallout, of which only a few of the more recent reports are referenced here. The reports that deal with the general chemistry and physics of decontamination are references 15, 16, 17, 18, 19, p4, p11, p12, and p13. Field-test and engineering-scale data are given in references 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, and p19. The application of these data to countermeasure systems planning is described in references 1 and 8.

In addition to cost of equipment, operating rates, manpower required, and radiation dose incurred, the efficiency of many of the reclamation methods depends on the physical and chemical nature of the fallout. For similar levels of radiation, fallout from detonations at sea consists mainly of sea water residues, and is most difficult to remove from surfaces; fallout from harbor detonations consists of sea water and harbor bottom soils and is more easily removed; and fallout from land detonations consists of contaminated soil particles and is easiest to remove. However, even for the latter case, decontamination of large areas is difficult and time consuming. The relative amounts removed by a method such as firehosing an asphalt road might be in the order of 30, 75, and 95 percent, for sea water harbor and land detonation fallout respectively. The amount of fallout, condition of the surface, and time of removal also influence the results. For this reason, the effectiveness of a washdown system on a ship (at sea) cannot be used as a meaure of effectiveness of a similar system on buildings (on land) without experimental verification.

Peripheral countermeasures in the operational recovery phase include (1) evacuation of nonessential persons to safe areas, (2) readjustment of operation schedules to reduce exposure times, (3) applied shielding such as sandbags around living and working areas. Whereas the presently employed concept in controlling radiation exposure is to exclude personnel from contaminated areas, the only feasible concept in radiological defense is just the reverse: the exclusion of radioactive material from clean areas.

SUMMARY OF STATE OF INFORMATION

The conceptual philosophy of an adequate radiological defense system is, at present, in a more advanced stage of development than are the supporting experimental data required for successful implementation of the system.

The main areas for which experimental data are needed are (1) shelter design and testing (habitability tests, contamination ingress, effects under firestorm conditions, operations in shelter related to outside conditions and future operations, communications problems, and control problems); (2) operational data necessary for testing many of the planning procedures such as those given

in reference 1; (3) reclamation procedures (improve reliability of data on presently available methods, develop and test new, dry, decontamination methods to replace presently recommended methods which require large amounts of water, develop and test of automatic or low-exposure decontamination methods, improve rates and techniques of application of present methods—especially on larger areas, obtain correlations of laboratory and engineering-scale data with data from nuclear tests—most all nuclear tests are not applicable since they are intentionally detonated not to produce fallout of the kind required); (4) definition of the radiological situation and development of countermeasures therefor during the final recovery phase from data on the transport of the radioactive elements in the region of heavy fallout from the radioactive particles into plants and animals used as foodstuffs; such data are required for the planning of necessary countermeasures for a resumption of normal living conditions; and (5) a proof test of a complete proposed countermeasure system under realistic attack conditions (a test in which the complete countermeasure system with all its tested components are put together and in which the countermeasure actions are continued through all the phases); such a test cannot be made under the biased influence of a weapons-development test, since it would take 5 to 10 years to complete, not counting the preparation time.

A Fallout Plotting Device

RESEARCH AND DEVELOPMENT TECHNICAL REPORT USNRDL–TR–127, NS 081–001, AND UNITED STATES ARMY, NOVEMBER 30, 1956

By E. A. Schuert, Physics, Techncal Objective AW–7; Radiological Capabilities Branch, L. B. Werner, Head; Chemical Technology Division, E. R. Tompkins, Head; Scientific Director, P. C. Tompkins; Commanding Officer and Director, Capt. Richard S. Mandelkorn, USN, United States Naval Radiological Defense Laboratory, San Francisco, Calif.

ABSTRACT

A fallout plotting device was developed. The method requires no drafting equipment and is ideally suited for field use. At Operation Redwing it was found that untrained personnel could quickly become proficient in its employment.

SUMMARY

The problem

A plotting device is needed to speed up forecasting where fallout will fall in the field. Such a device should require no drafting equipment but still accurately plot the required data in a manner compatible with the latest fallout model theories. It should be so constructed that untrained personnel can quickly become proficient with it.

Findings

Such a device was developed and tested at Operation Redwing. It proved to be satisfactory, and suitable for field operations.

ADMINISTRATIVE INFORMATION

This work was done under Bureau of Ships project No. NS 081–001, subtask 1, technical objective AW–7. The work is described in United States Naval Radiological Defense Laboratory annual progress report to the Bureau of Ships, DD form 613, of July 1956 (enclosure (1) to commanding officer and director, USNRDL Secret letter 3–905–471 EHC: dlc serial 0014921 of August 31, 1956). The plotter was tested at Operation Redwing, project 2.6.3, as described in subtask 4B of NS 088–001 of February 1956.

The work also is part of the technical program for the Department of the Army established between Department of the Army, Office, Chief of Research and Development and Bureau of Ships (joint agreement, Nov. 23, 1955).

INTRODUCTION

This paper describes a rapid technique for plotting "particle-size"[1] and "height" lines in mapping fallout from a nuclear detonation. Since this method,

[1] Particle-size lines are often referred to as hodographs or weighted hodographs.

one of hand computation, uses a fallout plotting device that requires no drafting equipment, it is ideally suited for field use. It was employed successfully at Operation Redwing where it was found that untrained personnel could quickly become proficient in its employment.[3]

The use of particle-size and height lines in mapping fallout is a standard technique employed in most analytical methods now in use. It simply describes a grid (fig. 1) on the earth's surface indicating where certain sizes of fallout particles, originating along a line source through the axis of symmetry of the cloud, will arrive and from what altitude they will come. These parameters are the basic data for describing the fallout pattern.

There are three requirements for determining this grid: the initial distribution of material in the atmosphere; the falling or settling rate of the material from its initial elevation; and the wind field through which the material is falling and by which it is being displaced.

The fallout plotting device computes the points of arrival on the earth's surface of a given particle size that originates at various altitudes within the mushroom cloud and its stem. Particles originating at elevations of every 5,000 feet, from the surface to 120,000 feet, are considered. In the construction of the device, account is taken of the variable speed of the settling particles due to changes in the vertical distribution of the atmosphere's density and viscosity. Aerodynamic falling equations were employed in its design. However, selection of particle falling speeds and altitude increments is arbitrary and not a fixed factor in the basic design of the plotter.

If the average wind speed and direction within a given altitude increment and the time required for a particle to fall through it are known, then the horizontal displacement of the particle can be computed for that altitude layer. Knowledge of the particle's point of arrival on the surface may be deduced from tracing a settling particle as it is displaced by each wind in each altitude increment. Plotting trajectories for each particle size at every starting elevation is the first step in determining the resultant fallout pattern; however, the drafting involved is tedious and time consuming. This effort can be reduced greatly by plotting from the ground up, as is done in the construction of a hodograph. Such a plot is made by starting at ground zero and working up through the altitude increments to the desired elevation. Although this technique does not plot the trajectory of the particle, it does define the arrival points on the surface of the earth of particles starting at each altitude increment (fig. 2).

DESCRIPTION AND USE OF DEVICE

To plot these size-lines one must make the preliminary computations of particle falling times through each altitude increment to obtain the displacement for various wind velocities. The plotter was designed with these computations built in, thereby speeding up the plotting process significantly.

The plotter consists of two parts, a base for direction or azimuth orientation and a wheel for distance or displacement. Since both of its parts are constructed of clear plastic, the plotter does not obscure the map over which it is placed. The base consists of a wind-rose having a radial line at each 10° interval on the compass. The base (fig. 3) has a narrow slot along the 180° line. If a given wind direction (in degrees from which the wind is blowing) is selected and its radial line oriented to north on the map (parallel to the north-south grids), the 180° slot becomes oriented in that direction in which a falling particle will be displaced. Thus by orienting the base of the plotter as described for any measured wind direction, the vector azimuth for the particle can be drawn through the slot of the plotter base.

The wheel (fig. 4) is pivoted at the center of the base. It has 24 equispaced radial slots. Each slot represents an altitude increment of 5,000 feet. Concentric circles intersect the radial slots to form a scale of wind speed in knots. Since the particle falling speed is a function of the atmosphere's density and viscosity and since these factors vary with altitude, the wind speed scales are so weighted

[3] A USNRDL report which will describe the detailed techniques of forecasting used at Operation Redwing and how the employment of the plotter was adapted to consider time variation of the winds is in preparation.

and the indicated length of the scale actually represents the horizontal displacement of the particle through the altitude layer of interest.

To obtain the distance the particle is displaced along its azimuth, the wheel is rotated until the proper altitude layer is alined with the 180° slot in the base and a line is plotted on the map.

It should be remembered that the weighted scales of wind speed fix the map scale, which in this case was 1 : 970,000 or 1 inch = 13.2 nautical miles. Different wind speed wheels have been constructed for several particle sizes; at present four wheels have been made.[3]

In plotting a size-line with the fallout plotter (fig. 5) one uses the same technique as one does when employing a drafting machine. However, all computations of horizontal displaced distance the particle experiences when falling through a given altitude layer are eliminated.

To plot a size-line or a trajectory, the following steps are necessary:

1. Rotate the wheel until the desired altitude increment coincides with the 180° slot in the base.
2. Place the plotter with the zero value of the wind speed scale over the given point and orient the base so that the radial line, showing the direction from which the wind blows, parallels the north-south grids of the map.
3. Draw a wind speed vector through the coincident slots.
4. Continue the process using the tip of the vector just drawn as the next point.

In constructing the prototype plotters certain specialized parameters were used in making the computations; for example, atmospheric density and viscosity were computed for a Marshall Island atmosphere, particle parameters were typical of coral fallout and special aerodynamic falling speed equations were used. Any of these variables as well as altitude increments may be so selected that a similar plotter for specialized or more general input data becomes possible. Also if one wished to assume a constant falling rate for a given size particle the wheel could be eliminated and the single wind speed scale laid out along the 180-degree slot on the base.

Figures 6A, 6B, 6C, and 7A, 7B, 7C are reproductions of the component parts of the four plotters that have been constructed. These figures can be used to construct a set of plotting devices. A reference scale has been added on each figure to relate the reduced drawings to their original size wherein the scale relationship was 1 : 970,000.

A Fallout Forecasting Technique With Results Obtained at the Eniwetok Proving Ground [Draft]

E. A. Schuert, USNRDL TR-139, United States Naval Radiological Defense Laboratory, San Francisco, Calif.

ADMINISTRATIVE INFORMATION

The work described herein is a part of the research sponsored by BuShips and the United States Army and locally designated as program 2, problem 3, phase 3. Its technical objective is AW-7 and it is described on RDB card NS 081-001.

SUMMARY

The problem: A fallout forecasting technique is needed to qualitatively describe the fallout hazard resulting from nuclear detonations. This technique should have such flexibility that its employment is valid for field use.

Findings: A summary of the latest experimental and theoretical considerations has resulted in the development of a technique whose complexity is dependent on the required accuracy of the results desired. This technique has been satisfactorily tested at the Eniwetok Proving Grounds for land surface and water surface bursts.

ABSTRACT

A generalized fallout forecasting technique is presented with detailed computations of input parameters for use in the Marshal Islands.

Results obtained at a recent weapons test are briefly discussed by comparison of forecast fallout with preliminary measured data.

1. INTRODUCTION

Fallout research continues to seek a theoretical working model that will describe in detail the mechanism of fallout. Aside from this long-range problem, consideration must be given to making available a working tool that will meet the needs of the military for solving fallout problems in the field. Such consideration requires a simplified rapid system capable of producing qualitative if not quantitative results.

Within a program studying fallout at a recent weapons test operation there was a fallout forecasting assignment that had many aspects of the practical

field problem yet, at the same time required quantitative results for use in reducing other data. This program needed positioning data such that three ships could be located properly in the fallout to obtain data on its parameters. Also, aerial and oceanographic survey projects required knowledge of the fallout to instigate their navigational procedures properly.

To meet these requirements a technique for rapid fallout forecasting was developed which not only satisfied the needs of the fallout program but also was accurate enough to allow comparison between meteorological aspects of model work and results obtained from surface measurements. This technique was restricted to describing quantitatively the perimeter of the fallout, the axis of the "hot line," and to determining the time of arrival of fallout throughout the pattern. No attempt was made to quantitate the expected levels of gamma activity or to develop radiation contour lines.

The task force employed a fallout prediction unit at this operation for determining the safe time to detonate the test devices. Many of their techniques for forecasting were similar to those described in this report, however, their problem was of a different nature than that of the fallout program. Several of their methods were unique in that portable analog computers were tested as field instruments. These computers permitted consideration of many complex parameters. One, in particular, obtained essentially an instantaneous solution to the problem once the meteorology was available.

The fallout program and the task force prediction unit functioned independently. It was not feasible for the two to employ the same technique because the postshot variability of the winds aloft were especially critical in ship-location problems in the fallout program. This problem will be discussed in detail later.

1.1 *Objective*

This report describes a technique of forecasting fallout employed at a recent weapons-test operation. The results obtained in the field are discussed as examples of the reliability of the techniques. Although the technique was designed for analysis of land surface detonations where the fallout is particulate, its application to water surface detonations is considered.

2. FORECASTING TECHNIQUE

The forecasting technique uses many ideas from fallout model work. Several simplifications as well as a plotting device have been developed to the end that the time involved has been reduced greatly without sacrificing accuracy. In general, an initial source of activity is defined describing the "stabilized" nuclear cloud by appropriate spatial and size distributions of radioactive particles. These particles are tracked to the earth's surface by considering their falling speeds and effects of the winds existing aloft.

2.1 *Basic considerations*

In some cases the input parameters for the forecasting technique were obtained from weapon-test measurements. In others where data were lacking, the parameters were derived from theory.

2.1.1 *Source model*

The optical or visible dimensions of the initial cloud from a nuclear detonation have been documented in past weapons tests. Available data describe such parameters as height to base of mushroom, height to top of mushroom, and mushroom diameter all as functions of time. Vertical rise stabilizes in approximately 6 min post detonation. This time is independent of yield, however, the expansion of the mushroom diameter particularly for the megaton devices continues for perhaps 30 min. Available diameter measurements have not been made in excess of H+10 min, however, fairly reliable data are known for the optical cloud dimensions as functions of yield to H+10 min. The ultimate cloud diameter can be extrapolated from low-yield curves and some qualitative data. Figures 1 and 2 present values of the cloud dimensions from past tests. The source model was assumed cylindrical having, for a given yield, these dimensions. Its stem diameter was taken as 10 percent of mushroom diameter.

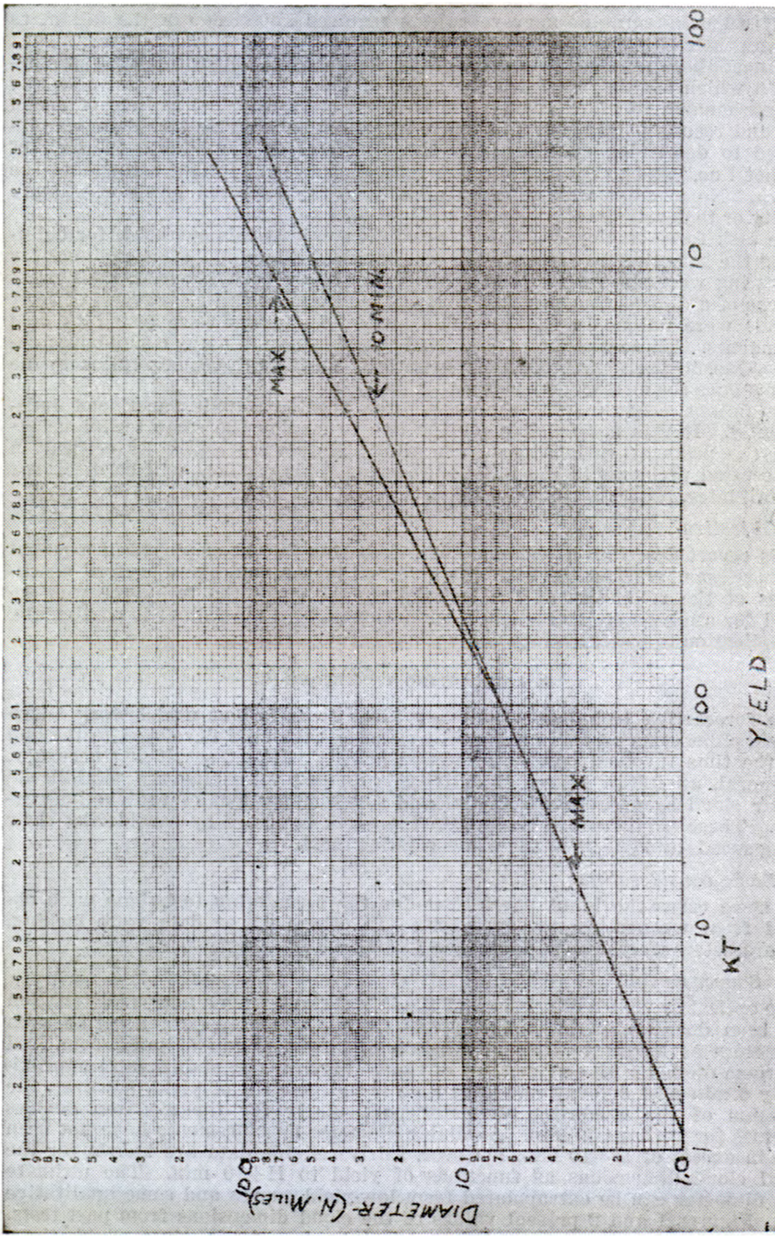

Figure 1.—Mushroom diameter as a function of yield.

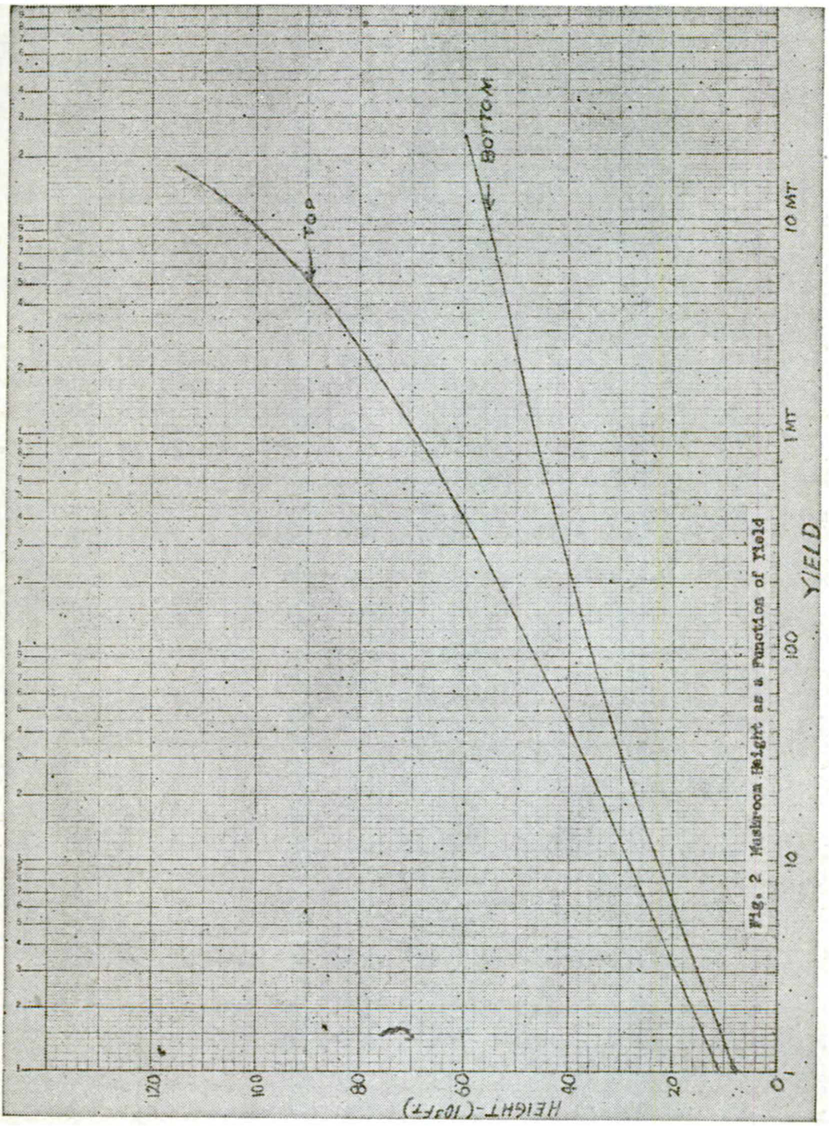

Fig. 2 Mushroom Height as a Function of Yield

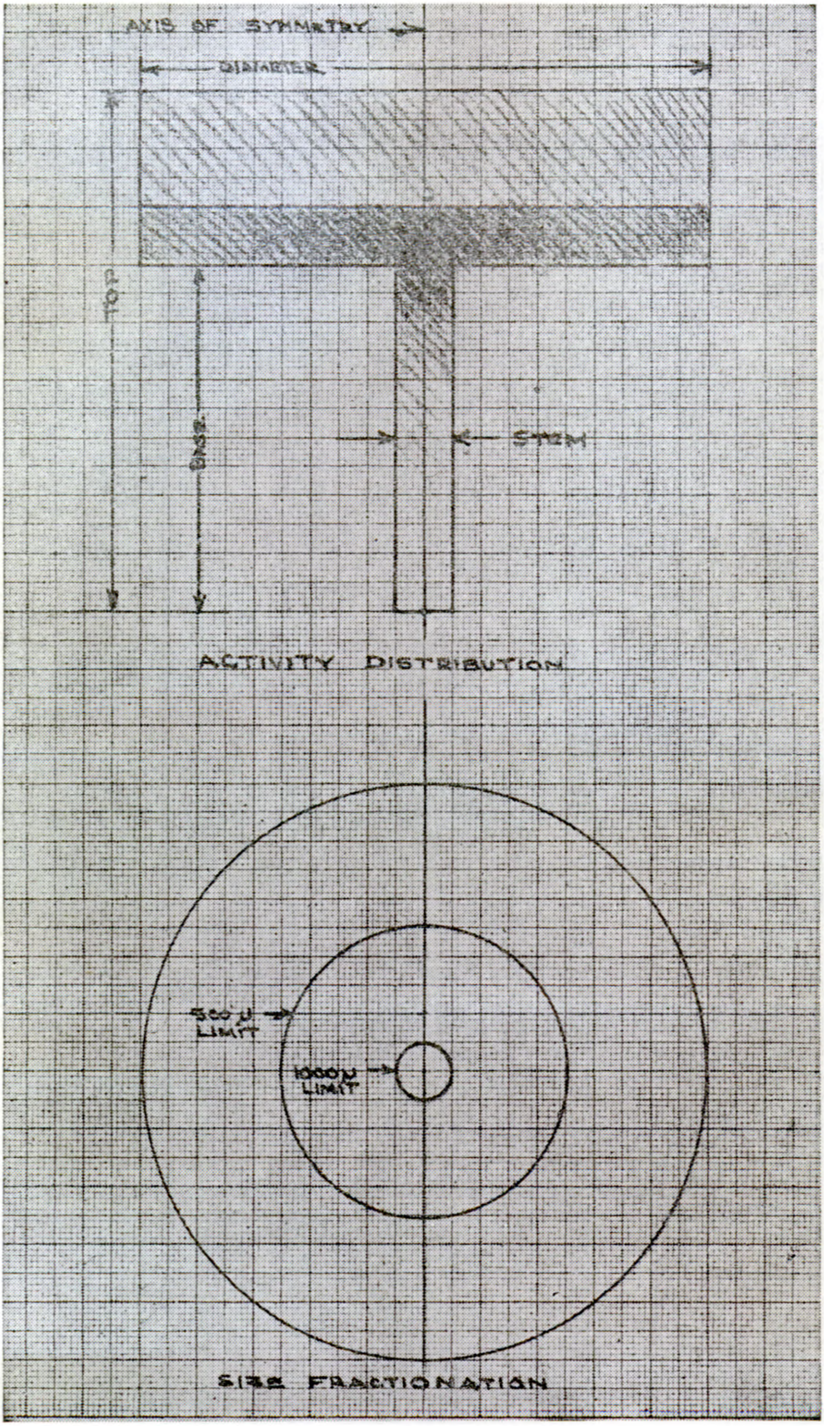

FIGURE 3.—Source model.

2.1.2 *Activity distribution in source model*

The great part of the activity was assumed to be concentrated in the lower third of the mushroom. The lower two-thirds of the stem was ignored; the remainder of the stem and upper two-thirds of the cloud were weighted lightly. This description (fig. 3) of the activity distribution within the cloud appeared most reasonable in the light of available data and logical theoretical considerations. The activity was concentrated nearer the axis of symmetry of the cloud than at its outer edges.

2.1.3 *Particle size distribution in source model*

All particle sizes were assumed at all elevations within the cloud except the lower two-thirds of the stem. However, to obtain agreement with past fallout measurements and with the optical diameter of the mushroom, it was necessary to fractionate the particle size distribution radially within the cloud. Otherwise, the computed fallout area about ground zero would be too large. The fractionation was specified as follows: particles of 1,000 microns in diameter and larger were restricted to the inner 10 percent of the mushroom radius or approximately the stem radius; those from 500 to 1,000 microns in diameter were limited to the inner 50 percent of the cloud radius. Since the relation of activity to particle size is some function of the particle diameter this fractionation tends to concentrate the activity about the axis of symmetry of the cloud.

2.1.4 *Particle falling speeds or settling rates*

Computations of the terminal velocities of the particles were based on aerodynamic considerations for a still atmosphere having temperature and density distributions typical of the Marshall Islands atmosphere in the spring months.

Experimental data from past tests at Eniwetok Atoll indicated that the particles were irregular in shape and had a mean density of 2.36 g/cu cm.

It can be shown that particles falling at their terminal speed experience three types of flow in a fluid: streamline or laminar flow where viscous forces predominate, ($10^{-4} \leq R_e \leq 2.0$); intermediate flow where inertia forces predominate, ($2 \leq R_e \leq 500$); turbulent flow where inertia forces predominate, ($500 \leq R_e \leq 10^5$). Below a Reynolds number of 10^{-4} certain corrections must be applied to the equations because the particle diameter approaches the mean free path of the fluid medium; the region above a Reynolds number of 10^5 is important only in ballistics. These limiting cases will not be discussed here.

The parameters actively affecting a particle's falling speed are: its weight, its drag coefficient, its density, as well as the fluid density and fluid viscosity.

Most empirical equations developed in past experimental work have been for spheres dropped in various liquids. Some work has been done on irregular shaped particles and some done in wind tunnels. The equations[1] used to determine the falling rates for particles in a fluid medium follow.

For Streamline motion, $10^{-4} \leq R_e \leq 2.0$

$$V_s = K_s \left(\frac{\rho - \rho_o}{\rho_o}\right) (d^2) \left(\frac{\mu}{\rho_o}\right)^{-1} \qquad (1)^2$$

where V_s = terminal velocity in cm/sec
ρ = particle density in gms/cm^3
ρ_o = fluid density in gms/cm^3
d = particle diameter in cm
μ = absolute viscosity of fluid in poises
K_s = constant incorporating gravity
= 54.5 for spheres
= 36.0 for irregular shaped particles.

The limiting diameter to which Eq. 1 holds is

$$d' = \left(\frac{36\mu^2}{g\rho_o(\rho - \rho_o)}\right)^{1/3}$$

for spheres and

$$d' = \left(\frac{54.4\mu^2}{g\rho_o(\rho - \rho_o)}\right)^{1/3}$$

for irregular shaped particles.

---

[1] J. M. Dallavalle, Mircomeritics, Pittman Publishing Corp., 1948.

For Intermediate motion, $2.0 \leqq R_e \leqq 500$

$$V_I = K_I \left(\frac{\rho - \rho_o}{\rho_o}\right)^{2/3} \left(\frac{\mu}{\rho_o}\right)^{-1/3} d_o \qquad (2)^{2}$$

where $d_o = d - \xi d'$
$\xi = 0.4$ for spheres
$\xi = 0.279$ for irregular shapes
d' = limiting diameter to which streamline motion applies
$K_I = 30.0$ for spheres
$= 19.0$ for irregular shapes.

The limiting diameter to which the Eq. 2 holds is

$$d'' = 43.5 \left(\frac{\mu^2}{g\rho_o(\rho - \rho_o)}\right)^{1/3}$$

for spheres

$$d'' = 51 \left(\frac{\mu^2}{g\rho_o(\rho - \rho_o)}\right)^{1/3}$$

for irregular shapes.

For Turbulent motion, $500 \leqq R_e \leqq 10^5$

$$V_T = K_T \left[\left(\frac{\rho - \rho_o}{\rho_o}\right) d\right]^{1/2} \qquad (3)^{2}$$

$K_T = 54.6$ for spheres
$= 50.0$ for irregular particles.

The question of particle diameter becomes puzzling when the equations are applied to irregular shaped particles. Although the equations for irregular shaped particles cannot be applied to an individual particle, they are assumed valid in establishing the average falling rates of many irregular particles clustered about this defined size.

2.1.5 Marshall Islands atmosphere

Marshall Islands atmospheric conditions determined the values for the density and viscosity parameters used in computing particle falling rates. Available data on the temperature, pressure, density, and viscosity as functions of altitude for the atmosphere common to the Marshall Island area in the spring months follow.

It was not possible to use a "standard atmosphere" in this problem because such use introduced a large error in the particle falling rate at high altitudes. This error originates primarily because of the assumed isothermal layer above the tropopause.

2.1.5.1 Temperature distribution

From the weather data published by Task Force Weather Central at Operation Castle, four published radiosonde runs obtained temperature measurements to high altitudes:

March 1, 1954, 0600 M Bikini
March 27, 1954, 0600 M Bikini
April 7, 1954, 0620 M Bikini
April 26, 1954, 0610 M Bikini

No data were available above 67,000 feet. Fortunately two of these runs penetrated the tropopause which was located at approximately 55,000 feet. To extend the measured data beyond 67,000 feet climatological averages [3] for latitude 12° North were employed. Agreement with measured data was satisfactory except for the range from 50,000 to 65,000 feet where the climatological data indicated a well-defined isothermal layer. The most significant finding from the measured data was the complete lack of an isothermal layer above the tropopause. Instead, a distinct and rapid inversion was observed which when extrapolated as a straight line agreed with the climatological data above 70,000 feet. Since the atmosphere was to be defined to 120,000 feet further extrapolation was necessary. The only temperature data available at these higher altitudes were taken by rockets [4] over White Sands, N. Mex. A plot of 3 points from the rocket data justifies to some extent a continued extrapolation of the curve to 120,000 feet.

[2] These equations were taken from reference 1; however, certain constants have been reevaluated.
[3] Brunt, David, Physical and Dynamical Meteorology, the University Press, 1941.
[4] Chief of Naval Operations, A Study of the Atmosphere Between 30,000 and 100,000 Feet (preliminary report), September 1948.

Therefore the profile of the vertical temperature gradient (fig. 4) was based on measured data to 67,000 feet and extrapolated to 120,000 feet on the basis of supporting climatogical data and temperature measurements made at high altitudes with rockets.

2.1.5.2 *Pressure distribution*

Published high altitude measurements of the pressure distribution were obtained on two occasions at Operation Castle. These measurements [5] were made at Bikini on April 7 and 26, 1954, and were not taken above 65,000 feet. Above this altitude the pressure was extrapolated as a straight line on semilog paper to 120,000 feet. Agreement with published rocket data from White Sands, N. Mex., was good to 90,000 feet (fig. 5).

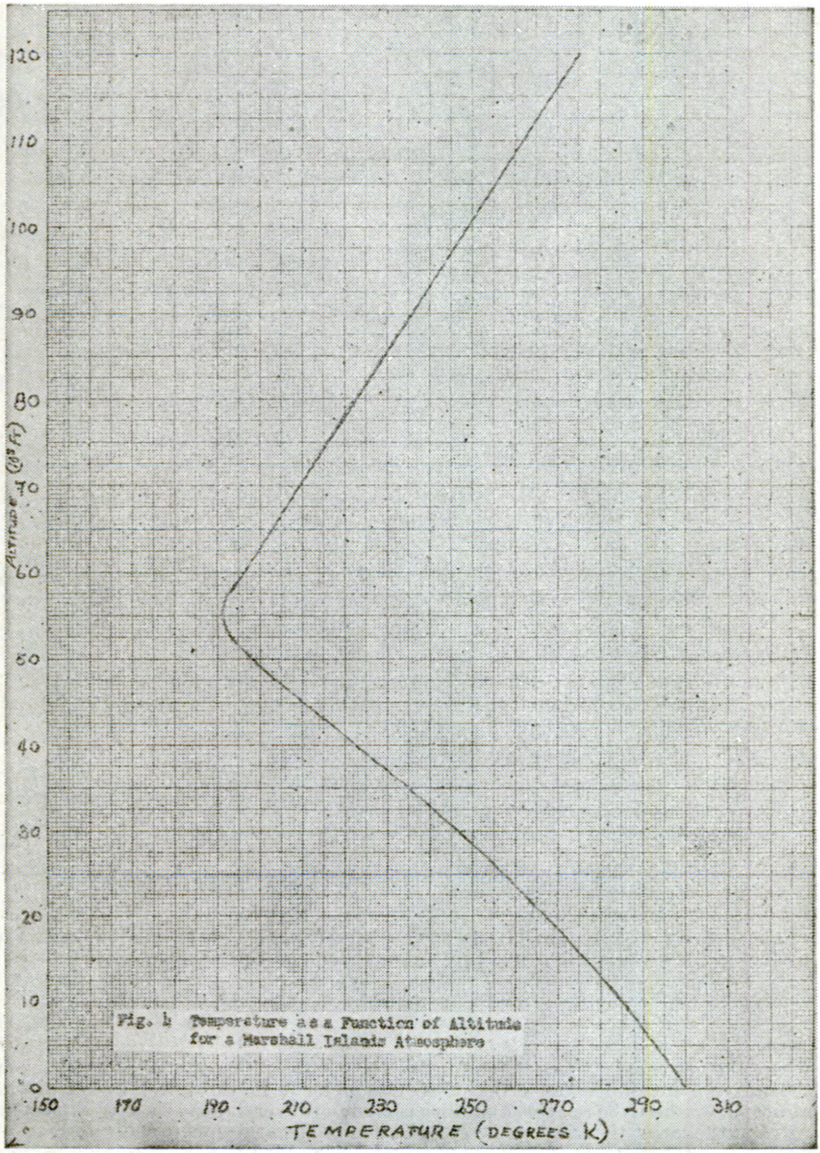

Fig. 4 Temperature as a Function of Altitude for a Marshall Islands Atmosphere

[5] Hq. T. U.–13 operation memo No. 14, April 30, 1954.

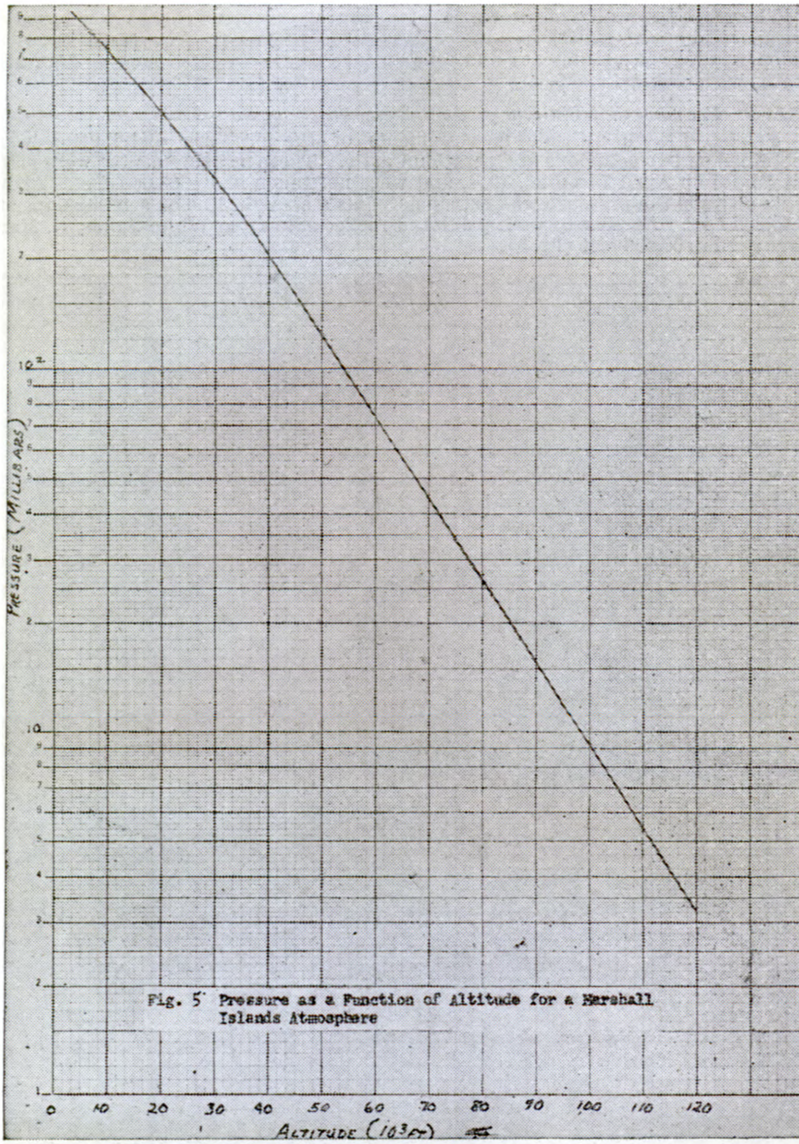

Fig. 5 Pressure as a Function of Altitude for a Marshall Islands Atmosphere

2.1.5.3 Density distribution

The density distribution of the atmosphere (fig. 6) was calculated from the perfect gas law using the above pressure and temperature distributions,

$$\rho = \frac{P}{RT}$$

where the gas constant was taken for dry air. This assumption of no moisture in the mixture introduces an error of several percent in the lower layers of the atmosphere where the relative humidity is high; however, it can be safely neglected. As well, the latest theories on the composition of the atmosphere indicate it to be constant to altitudes above 150,000 feet which justified the assumption of a non-varying gas constant.

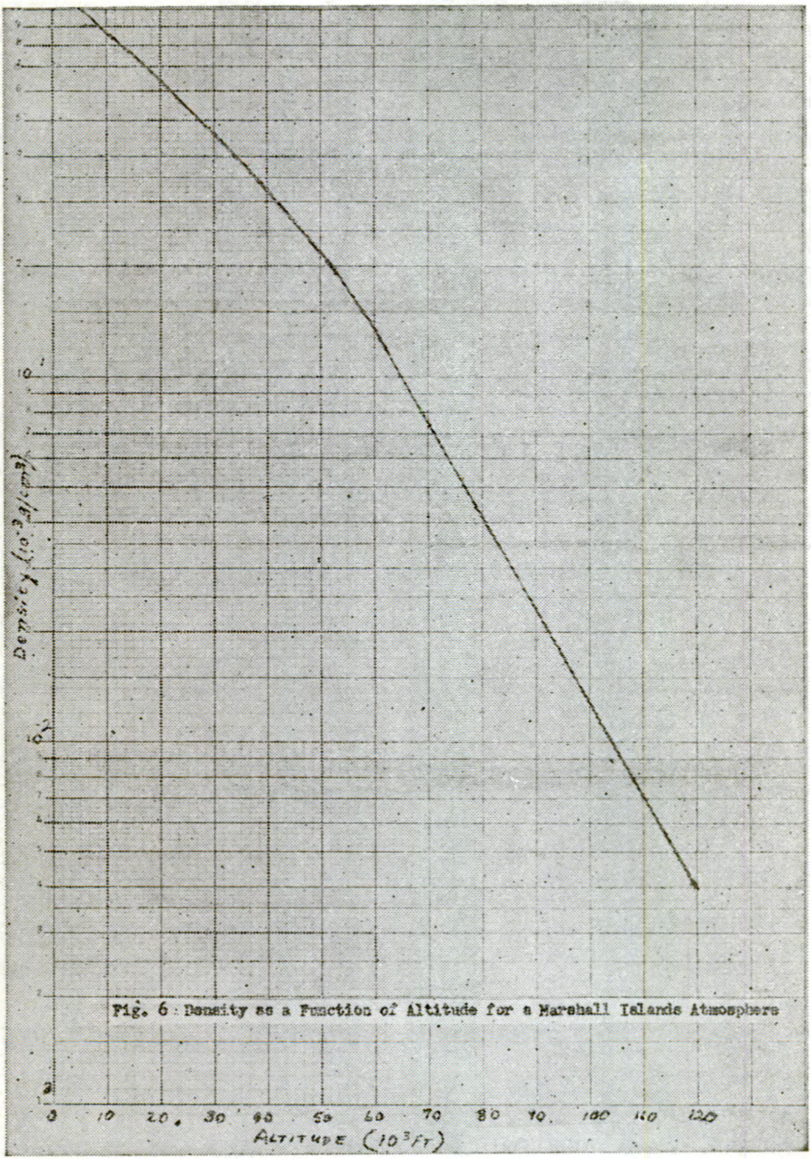

Fig. 6 Density as a Function of Altitude for a Marshall Islands Atmosphere

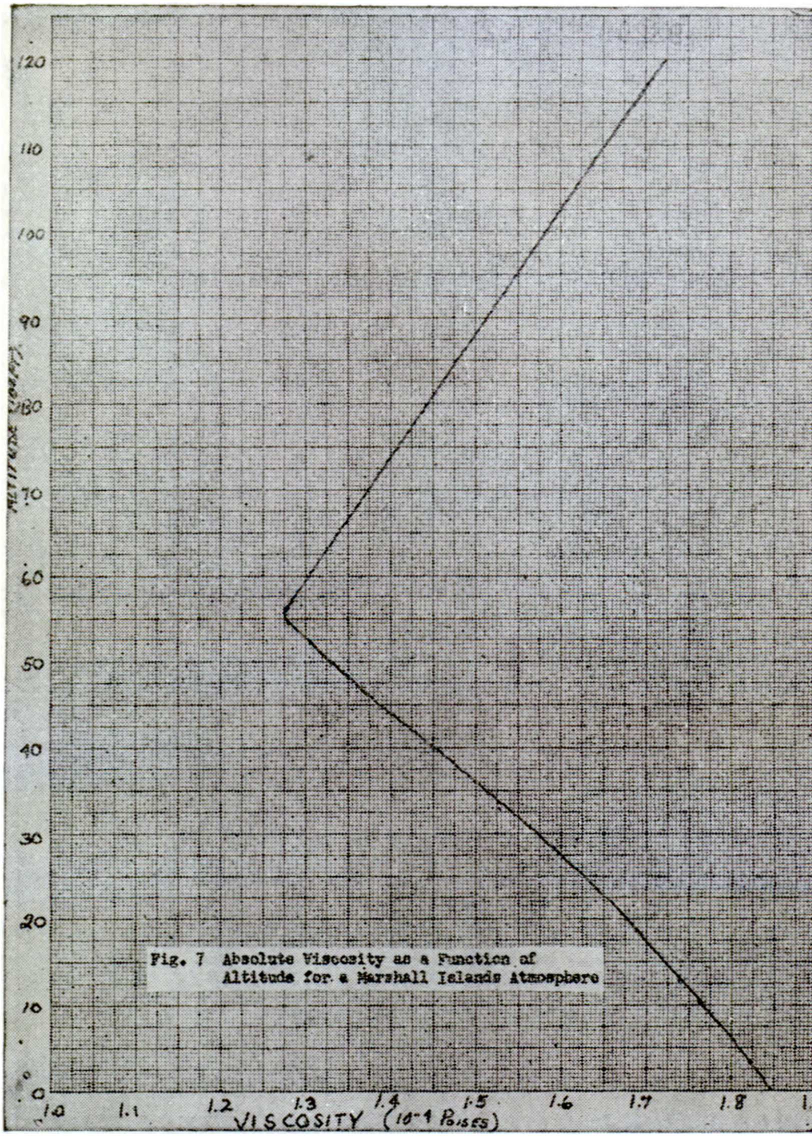

Fig. 7 Absolute Viscosity as a Function of Altitude for a Marshall Islands Atmosphere

2.1.5.4 *Viscosity distribution*

The variation of absolute viscosity with altitude was computed from the observed temperature distribution using Sutherland's formula,[6]

$$\mu = u_o \left(\frac{T_0+114}{T+114}\right)\left(\frac{T}{T_o}\right)^{3/2}$$

$$u = 0.01709 \left(\frac{387.17}{t_i+114}\right)\left(\frac{t_i}{273.17}\right)^{3/2}$$

where t_i equals temperature in degrees Kelvin and μ is viscosity in centipoises. These data are plotted in figure 7.

The data on pressure, temperature, density, and viscosity in 1,000-foot intervals to 120,000 feet are summarized in table 1.[7]

TABLE 1.—*Table of temperature, pressure, density, and viscoscity of the atmosphere over the Marshall Islands during the spring*

Altitude (feet)	Temperature °K	Pressure (Mb)	Density ($g/cm^3 \cdot 10^3$)	Viscosity ($poises \cdot 10^4$)

[6] Smithsonian Physical Tables, 1954.

[7] A great deal of excellent upper air data for the Marshall Islands was obtained at Operation Redwing in 1956. Reduction of these data will result in a much better description of the Marshall Islands atmosphere than has been previously available.

2.1.5.5 Terminal velocity computations

The average falling speed through 5,000-foot layers was computed for 4 particle sizes over an altitude range from 0 to 120,000 feet. In these computations all in-flight transition of the particles from streamline to intermediate flow had to be considered through use of the plot shown in figure 8.

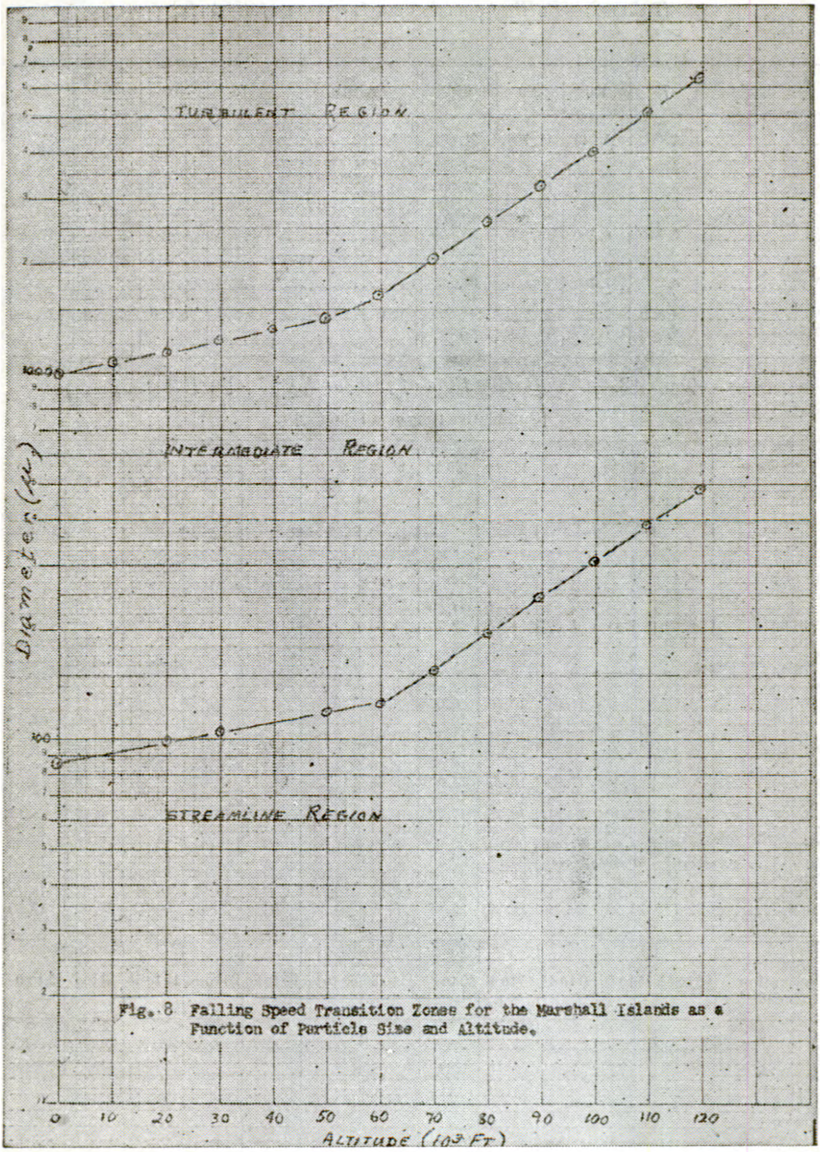

Fig. 8 Falling Speed Transition Zones for the Marshall Islands as a Function of Particle Size and Altitude.

Four particle sizes (75 μ, 100 μ, 200 μ, and 350 μ diameter) were employed since there was evidence from past tests that the 75 μ particle defined the limiting distance of fallout of interest and the larger sizes best described the pattern wihin this limit. Table 2 presents the falling speeds computed for the 4 sizes. Tables 3, 4, 5, and 6 display the cumulative time of fall from a given altitude for these particle diameters.

TABLE 2.—*Falling speeds as a function of altitude*

[Falling speeds (foot-hour)]

Altitude	75	100	200	350	Altitude	75	100	200	350

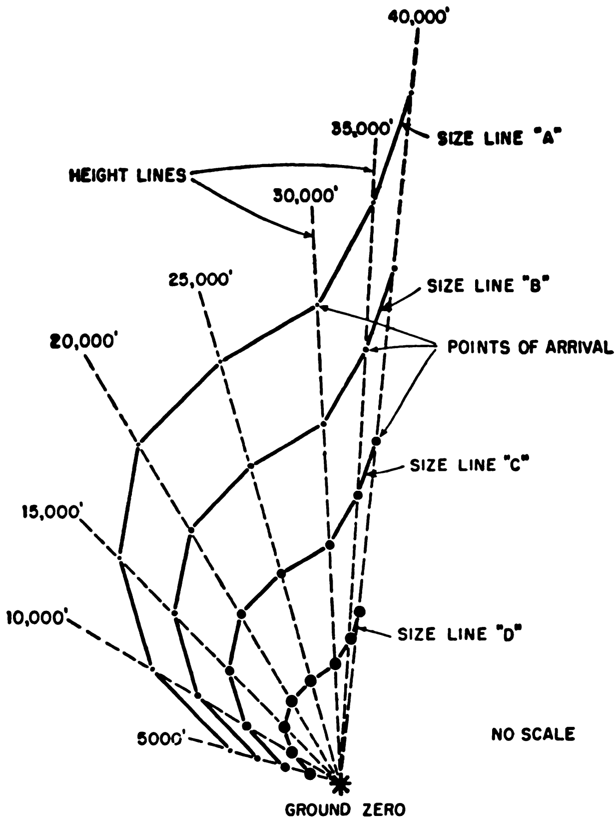
2.1.5.6 Meteorological procedures

It is necessary to have available the best possible description of the winds aloft to determine the arrival points of particles of various sizes originating at various altitudes. Such data are usually available from the normal upper air soundings routinely taken by Weather Bureau and military meteorological stations. Although wind velocity as a function of height varies continuously, it can be described by an average speed and direction in discrete layers. Such averaging can best be obtained from the WBAN–20 form where the original data are recorded. The technique employed in this report was to divide the atmosphere into layers 5,000 feet thick and determine an average speed and direction for each layer. When the average falling speed of particles through these 5,000-foot layers and the speed and direction of the wind are known, horizontal displacement can be computed. Thus for each particle size a vector may be drawn for the average particle displacement in a particular 5,000-foot layer. Addition of such vectors from all layers describes the trajectory projection of a particle of given size. Similar plotting for all particle sizes originating at all elevations within the cloud source will map the fallout on the earth's surface.

This technique is valid for any atmosphere that has negligible vertical motion and is in a steady state condition with respect to the horizontal winds during the time needed for the slowest particle to fall from the highest altitude to the ground. Such an assumption is not realistic for situations arising from many of the megaton devices because 15 to 20 hours are necessary to establish the fallout area. Consequently, when computing particle trajectories, an attempt should be made to consider how the wind varies with time, how it varies with distance from ground zero, what effect vertical motions have on particle falling speeds, and how they vary with space and time. Such considerations complicate computation of trajectories extremely. In most cases valid input data describing these variables are not available. This phase of the problem is discussed below.

2.2 Plotting technique

The use of "particle size" and "height" lines in mapping fallout is a standard technique employed by most analytical methods. This technique simply describes a grid (fig. 9) on the earth's surface indicating where fallout particles of certain sizes will arrive and from what altitude they came. These parameters are the basic data for describing the fallout pattern.



NOTE: Four particle sizes originating at altitudes up to 40,000 feet in a hypothetical wind field

FIGURE 9.—Basic Fallout Plot Showing Grid of Size Lines and Height Lines.

Assuming steady state meteorological conditions without vertical motion or space variation of the winds, it is very easy to construct a grid describing arrival points on the earth's surface for particles of various sizes originating at different altitudes. This grid is constructed by ignoring the horizontal distribution of particles in the cloud model and by plotting those trajectories that originate along the line source describing the vertical axis of the cloud.

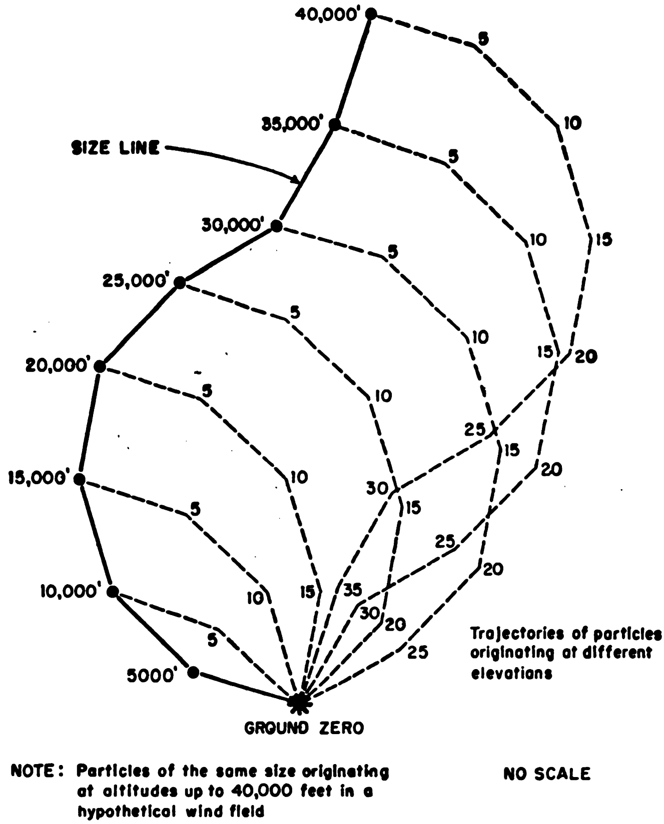


FIGURE 10.—Comparison of plotting techniques either by use of trajectories or by use of a size line.

Plotting trajectories for each particle size at every starting elevation is the first step in determining the resultant fallout pattern; however, the drafting involved is tedious and time consuming. This effort can be reduced greatly by plotting from the ground up, as is done in the construction of a wind hodograph. Such a plot is made by starting at ground zero and working up through the altitude increments to the desired elevation. Although this technique does not plot the trajectory of the particle, it does define the arrival points on the surface of the earth of particles starting at each altitude increment (Fig. 10). To plot these size lines one must make the preliminary computations of particle falling times through each altitude increment to obtain the displacement for various wind velocities as described earlier in section 2.1.5.5.

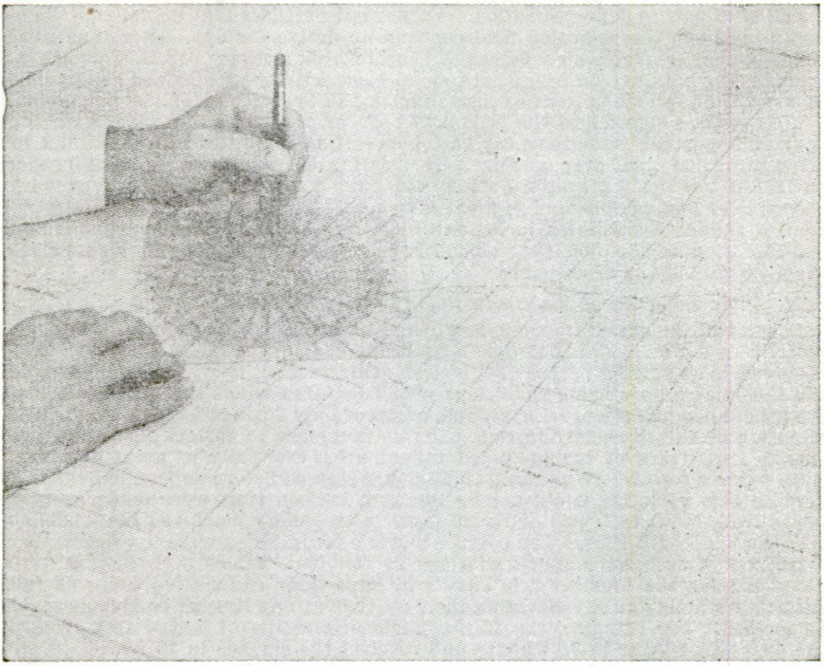

FIGURE 11.—Fallout plotting device.

A plotting device (fig. 11) has been described elsewhere[8] which facilitates the computations required for the size lines of the fallout pattern. Such devices were constructed for 4 particle sizes: 75, 100, 200, and 350 μ in diameter. With these plotters trajectories or size lines can be plotted from any elevation to 120,000 feet for the 4 particle sizes. The plotters automatically account for the variable particle falling speed. They also eliminate the need for drafting equipment. After establishing the particle arrival points by either the use of size lines or trajectories, height lines can be constructed. These lines joining surface zero with the arrival points of all particles from the same elevation are most descriptive for they define the path along which all particle sizes will deposit from that originating altitude.

The height lines describing the fallout from the lower portion of the mushroom immediately establish the "hot line." The "hot line" is best defined as that portion of the fallout area wherein the highest levels of activity are found relative to the adjacent areas. Under most meteorological conditions this area is described by a line from surface zero that coincides with the height lines from the altitude layers that include the base of the mushroom; for the source model was so defined to concentrate the activity in this volume.

Since the plotted grid of size lines and height lines was based on a line source of activity each particle point must be expanded to the appropriate cloud or stem diameter from which it originated. This expansion, after taking into consideration the radial particle size fractionation in the source model, defines the perimeter of the area. One then has a map indicating the fallout area and the path of expected highest activity.

Curves of time of arrival of fallout through the pattern are established by simply assigning the appropriate value of falling time to each expanded circle about the arrival points and by constructing from this network of values isotime contours that indicate the earliest time at which fallout will arrive at a given distance from the shot point. The determination of the time of cessation of fallout at any location may be plotted similarly, however, one is faced with the

[8] E. A. Schuert, A Fallout Plotting Device, USNRDL Technical Rept. 127, February 1957.

question of how to define cessation. Very small particles that do not contribute significantly to the radiation field continue to arrive for days after time zero. Consequently, a plot which describes time to peak activity seems more meaningful. During the field operation time to peak activity was defined as the time of arrival of fallout particles originating in the lower third of the mushroom.

This method determines the fallout plot under conditions that do not involve several important meteorological variables. It is most valid for a fallout of short duration and over a relatively small area, for example, a 1-kiloton surface detonation. Megaton devices and large kiloton yields deposit primary fallout over long periods and to great distances. To map such extensive deposition of fallout necessitates inclusion of complex meteorological variables and consideration of the fact that clouds from these large detonations extend to great heights in the atmosphere.

2.2.1 Time variation of the winds aloft

In most of the observations made at the Eniwetok Proving Ground, the winds aloft were not in a steady state. Significant changes in the winds aloft were observed in as short a period as 3 hours. This variability was probably due to the fact that proper firing conditions which required winds that would deposit the fallout north of the proving ground, occurred only during an unstable synoptic situation of rather short duration. It was necessary to correct for this variation to keep track of the predicted fallout area, especially at great distances from surface zero where as much as 20 hours elapsed before deposition.

Since this variation could not be forecast, balloon runs were made every 3 hours from H+O to H+24 and each particle trajectory employed the winds as they changed with time. The correct particle trajectories were approached by a method of successive approximations as follows: Tables 3 through 6 were computed for the four particle sizes and gave their cumulative times of fall such that starting at any elevation their altitude at any time after H-hour could be located. For example, the 75-μ particle originating at 70,000 feet entered the 40,000-foot layer in 7.18 hours and reached the surface in 19 hours. Since new upper air observations were obtained every 3 hours it was assumed that the balloon released at H+O represented the winds aloft until H+3 hours and the balloon released at H+3 hours represented the winds until H+6 hours and so on. Therefore, as the particle settled to earth the appropriate winds aloft were applied to it.

The first step was to plot size lines for the particles based on the H+O hour winds. This established a fallout plot that assumed the winds would not change with time. When the H+3 winds became available a similar plot was made based on them. With the aid of tables 3 through 6 the particles starting at various elevations were located in altitude at H+3. These H+3 hour points are marked at the proper altitude on each size line. The two size lines, H+O and H+3 are then overlayed such that the H+3 hour points are conicident and the combined size lines determined with the aid of a light table. This is done by taking the upper portion of the H+O hour size line and the lower portion of the H+3 size line. This first approximation then assumes that the H+3 hour winds will remain steady for the remainder of the particles flight. The process is repeated using the combined size line and the new size line for the next set of wind data until the particle reaches the surface. Therefore for each new wind observation a closer approximation of the corrected time variable plot is made until ultimately the plot is quantitative.

2.2.2 Space variation

The preceding computations assumed that the winds aloft as measured at the point of detonation at a given time are the same throughout the area for that time. Since the fallout can deposit hundreds of miles from surface zero, ideally, one would like winds-aloft measurements throughout the volume traversed by the particles. Correction for space variation of the winds is then necessary, however, in most cases not as significant as is time variation. Most weather networks are not refined enough to allow quantitative correction for these errors.

2.2.3 Vertical motions

In applying particle falling speeds to the forecasting technique, it is assumed that the atmosphere has no vertical velocity. Computations made at the Eniwetok Proving Ground[*] to 50,000 feet indicated that large cellular vertical

[*] Under the direction of Comdr. Daniel F. Rex, Joint Task Force Seven Meteorological Center, Pearl Harbor, T. H.

motions in the atmosphere sometimes attained speeds equal to and greater than the settling speed of a 75-μ particle. A time-space correction should be made to the falling speeds of the particles to compensate for this parameter. However, in the work at the test site it was not possible to include this effect in the fallout forecasts. Certain anomalies discussed below may be due to such an effect and postshot analysis is being conducted to see whether they are resolved when the vertical motions have been taken into account.

3. DISCUSSION OF FIELD TEST RESULTS

The forecasting technique described was employed by the fallout program at the Eniwetok Proving Ground to satisfy certain project requirements. One project had three ships equipped to collect fallout and their positions had to be determined for most efficient collection; another sampled the ocean for fallout; while another made an aerial survey of the contaminated area. The navigational schedules for these latter projects were based on the forecast fallout pattern. Operations were controlled through the program control center aboard the task force command ship where the forecasts were prepared.

The meteorological data was received from the weather ship at Bikini Atoll as well as from weather stations at Rongerik Atoll and Eniwetok Atoll. Furthermore all forecasts made by the task force weather central at Eniwetok Atoll were usually available aboard the command ship by facsimile through the ships weather station.

Upper air measurements were made at Bikini, Rongerik, and Eniwetok Atolls every 3 hours starting at H—24 hour and continuing until H+24 hour for any given detonation. The frequency of observations was usually increased during the period from H—6 to H—2 hours. The altitudes reached on the wind runs were remarkably high and gave perhaps the best set of winds-aloft measurements to date. The average termination altitude was approximately 90,000 feet with many runs over 100,000 feet. Such excellent coverage of the winds aloft was a major help in the fallout forecasting.

Fallout forecasts were made every 3 hours starting at H—24 hour using the *measured* winds available at the time. This process was continued up to shot time and from then on the technique of correcting for time variation was employed every 3 hours until the fallout event was completed. It was not feasible to correct for space variation and vertical motions during this period because of lack of time and data.

3.1 Fallout plots

The fallout forecasts determined at the weapons-test operation were based entirely on measured data and quantitatively considered time variation of the wind. No space variation corrections or computed values of vertical motions were employed in their construction.

The area of measured fallout from shot A is compared with the forecast fallout plot in figure 12. Figures 13, 14, and 15 are similar comparisons for shots B, C, and D. Although C and D were water-surface shots, it is evident that the forecasting technique succeeded in representing the measured fallout area as well as it did for the land-surface detonations, A and B.

The comparison is excellent for all shots except B and as yet the discrepancy betwen the forecast fallout area and that which was measured is unknown. There is some indication that consideration of vertical motions will have to be made for shot B during the time of fallout since computed vertical motions were significant in magnitude. Such analysis including space variation is being carried out at this time for all four detonations and the refined data will be published later.

4. SUMMARY

The fallout forecasting technique described in this report was successfully employed for both land surface and water surface detonations at the Eniwetok Proving Ground. With known meterological data such a technique will successfully qualify the area of fallout and indicate qualitatively the relative intensity of radiation.

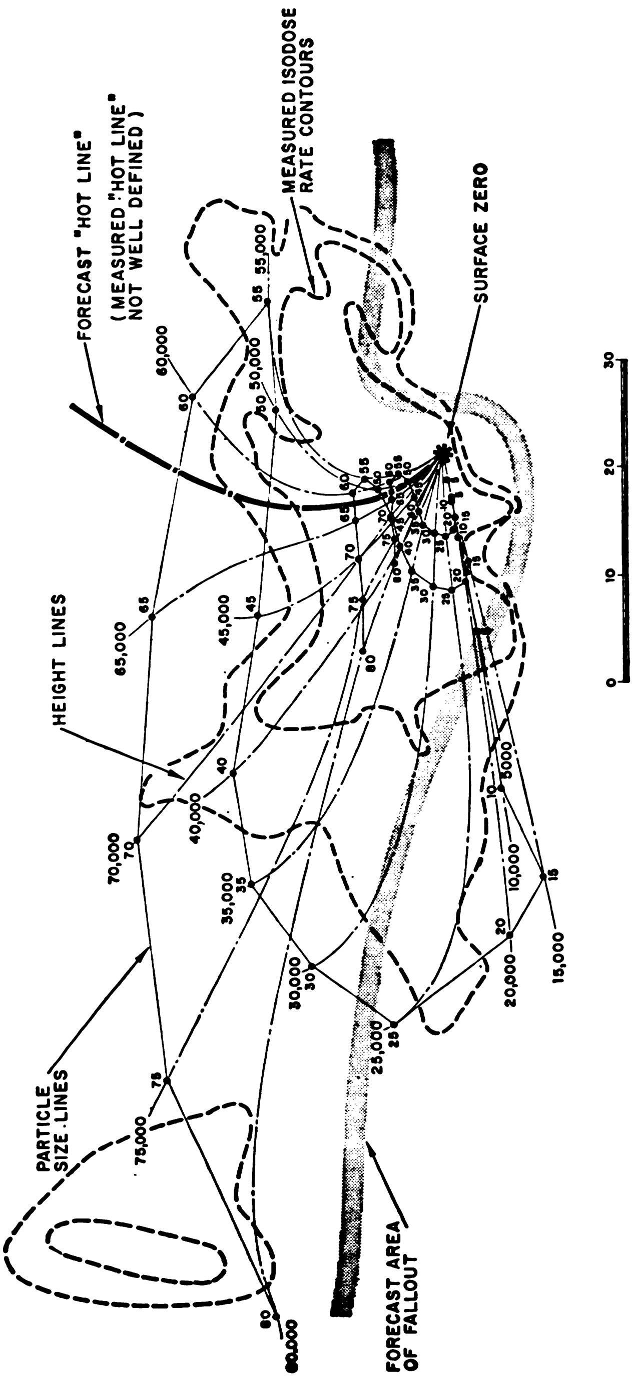

Figure 15.—*Comparison of fallout forecast with test results—shot D.*

Precise determination of the fallout area requires consideration of many complex meteorological parameters. However from the above analysis a practical field tool can be developed that in most cases will satisfactorily define the area of interest.

Mass Activity Relationships Derived From Fallout Measurements

Since fallout consists mainly of nonradioactive debris from nuclear detonations, the essential physical and chemical behavior of fallout is determined by the nature of the inert debris. For example, fallout from detonations on the surface of the ocean will consist of sea water, construction materials of the weapon, and radioactive materials, while fallout from a land-surface burst is produced from soil and target materials, weapon-construction materials, and radioactive elements. In terms of mass, or weight, the relative abundance of the radioactive elements is much less than 1 part in a million. Therefore, except for their radioactive properties, these elements would be extremely difficult to detect.

Accordingly, all major physical and chemical processes which deal with fallout require information on the relation of activity with the other bulk material. The simplest of these relationships is the ratio of activity to the gross mass or its inverse. A more complicated one would be the relation of activity to particle size.

In the fallout area, activity is commonly measured in terms of r/hr, and since r/hr is proportional to activity per unit area the equivalent mass quantity is, therefore, weight of fallout per unit area. For convenience in other computations, the relation of interest is defined as a ratio of mass per unit area to r/hr at a given time after burst; thus it is called the mass contour ratio and is given the symbol $M_r(t)$, since its value depends on the time after burst (due to decay). The generalized scaling equation for the mass contour ratio is

$$M_r^{\lambda}(t)=\frac{f\cdot KA_{\lambda}W^{(n-1)}}{bR(t)[a_{FP}(t)+a_I(t)]} \tag{1}$$

in which

1. W is the total yield of the weapon.
2. $a_{FP}(t)$ is the activity of the fission products in d/m per unit area for 10^6 fissions at time, t.
3. $a_I(t)$ is the sum of the induced activities in d/m per unit area for 10^6 fissions at time, t.
4. R(t) is the ratio of r/hr to d/m per unit area at time, t. If the ratio is computed for an ideal infinite plane, then $R(t)=uR_o(t)$ in which $R_o(t)$ is the computed ratio and u is a factor which accounts for the effect of the terrain on the radiation intensity; knowledge of the photon spectra of the FP + induced activities at time, t, are required to make a reliable calculation of $R_o(t)$.
5. b is the ratio of fission to total yield.
6. bW is then the fission yield (W^{-1} is in the numerator).
7. K is a conversion factor relating the choice of units for W (lbs. of TNT, KT, MT, etc.) to the number of fissions per unit of fission yield, and the units of area and mass desired.
8. $A\lambda W^n$ is the scaling relation for the mass of material removed from the crater. The constant $A\lambda$ depends on the height or depth of burst; it is usually given as a function of the scaled depth, λ, and λ is defined as the depth or height of the burst in feet divided by the cube root of the yield in equivalent lbs. of TNT.
9. f is the fraction of the total mass of material which is thrown out of the crater and gets mixed with the radioactive elements.

The equation constants have been evaluated from available data. The dependence of $A\lambda$ on λ is usually given in graphical form; the results of its use with available data is satisfactory within the limits of error of the data. The mass contour ratio, defined by Eq. 1, is a major parameter in evaluating decontamination results for fallout from detonations near land and harbors; it is also used to convert results from one condition of burst to another.

For high yield detonations, the relation holds, within a given error, up to within the heavy blast damage region; for smaller yields, and under ground bursts where large crater lips are formed and much inactive soil and debris are thrown randomly about, no given relation holds.

Relation of Radioactive Decay to Countermeasures

The fundamental concepts of a time-phased countermeasure system are based on the fact that the radiation intensity decreases with time. The time-history of the radiation intensity at some location in the fallout area starts when fallout arrives; the intensity increases or "builds up" to a peak sometime during fallout and then decreases when the decay rate is more rapid than the rate of arrival of fallout. After fallout ceases, the radiation intensity decreases with a rate determined by the half-lives and relative abundances of the radionuclides present in the fallout.

Knowledge of the shape of the radiation intensity time-history curve is required to determine what countermeasures can be used at different times after attack and what their requirements are. Mathematically, the areas under the time-history curve for various time periods give estimates of the radiation dosages that could be received during those periods without countermeasures.

In the early period, when the radiation intensity is rapidly increasing toward the peak, large dosages can be received in a very short time; therefore, in areas where the peak is higher than some given value, all personnel exposed to the radiation (for a given time) will become casualties. If these personnel are protected from radiation during this period, they will be able to perform their functions at a later time.

After the intensity decreases (due to decay), certain short-time controlled tasks can be performed in the open without risk of casualties.

The major short-time task is the reclamation of vital operations by decontamination or other actions which will reduce the dose to personnel over a subsequent period to an acceptable amount.

After a longer period of time only the very long-lived radionuclides remain. In fission products alone, the majority of these nuclides are beta emitters. Thus when the gamma emitters have decayed beyond a certain level as to be of no hazard to personnel, the only countermeasures required will be those that deal with ingestion of long-lived beta emitting nuclides.

Again, the guide for determining the appropriate time(s) of application of a given countermeasure(s), what the performance specifications should be, and how the operational application should be made all depend upon the degree of knowledge of the radiation intensity time-history curve—i .e. range of absolute magnitude of the intensities, areas involved for different yields, etc.

The dosage, or area under the intensity-time curve, is sensitive to the shape of the curve. One commonly used decay curve for estimating dosage is that described by the $t^{-1.2}$ function. Since this function is known to be only an approproximation, it is of interest to know to what degree it represents—or misrepresents—the true nature of the intensity-time curve; and, specifically, to what degree the dose estimates from its use differs from other theoretical curves which have given intensity-time curves similar to those observed experimentally. Integrated doses for various periods of possible exposure (stay times) at a series of entry times for a standard intensity of 1,000 r/hr (at $H+1$ hr) are given in table 1 for both the $t^{-1.2}$ function and a normal decay (for radioactivity from a hypothetical weapon in which the decay curve is a normalized average from a number of experimental decay curves) titled "Theoretical Decay" in the table. It may be noted that the intensity for the theoretical decay is higher than for the $t^{-1.2}$ until between 1 and 2 months after burst; after this time, the theoretical decay curve is lower.

The differences in dose between the two for different stay times is given in table 2; a generalizing of the tabulation is that the $t^{-1.2}$ function underestimates the dose for early entry and short stay time and overestimates the dose for late entry and long stay times. The magnitude and order in which the differences occur are considered to be operationally significant for planning purposes; therefore the $t^{-1.2}$ function is no longer used by the Military Evaluations Group of NRDL in its countermeasure evaluations investigations for military sponsors.

PHYSICAL CHEMISTRY OF FALLOUT AS IT RELATES TO DECONTAMINATION COUNTERMEASURES

GENERAL BACKGROUND

In countermeasures, the basic physical chemistry of fallout is concerned with the interactions of fallout with surfaces. These interactions are then related, in a practical sense, to an appropriate choice of reclamation procedures. Further, an understanding of the chemistry leads to a precise concept of the nature of fallout and to the significant properties of both the weapon and the target that combine to produce fallout of a given chemical nature as well as the implication of these properties on the countermeasure performance.

In radiological defense designed for nuclear attack there are three basic kinds of fallout of interest: (1) From detonations at sea, (2) from detonations on land, and (3) from detonations on harbor targets. The general description of the interactions of these kinds of fallout will aid in explaining some of the technical problems; some of the experimental data and techniques are also applicable to reclamation problems which might range from a laboratory spill of a small amount of activity to a reactor accident although none of these would ever approach the scope of the reclamation task envisioned in event of fallout from nuclear attack.

SEAWATER FALLOUT

Seawater fallout will consist of seawater, bomb structural and target materials, and radioactive products. The bulk of the material thrown up in a detonation at sea will be seawater of which about 3 percent of the weight is salt (mainly sodium chloride); the radioactive elements will be present at concentrations less than 1 part in a million. A high yield explosion will throw this material to such altitudes that much of the water can evaporate in falling back to earth; with lower yield explosions less will evporate. Depending on the humidity, in one extreme the fallout might arrive as wet, saturated salt particles and in the other as water droplets much like rain.

When these droplets or pseudo crystalline salt particles strike a surface (for simplicity, assume an impervious surface such as painted metal or wood) they will tend to stick where they land, and since fine mistlike particles travel almost horizontally more of them can strike and stick on vertical surfaces. Larger water droplets, however, when deposited in large numbers will fall more vertically and run off vertical surfaces.

Since the bulk material (salt) is water soluble and never completely dries out (or stays dried out) in the presence of water vapor in the atmosphere, the radioactive as well as the salt atoms (ions and colloids) can move about in water and diffuse toward the surface. Within several hours after deposition, the droplets will all evaporate to the same degree under the same conditions and reach the same equilibrium state with respect to the surface.

In this environment each radioactive atom has some freedom of movement and each kind (element) will interact with the surface in its own characteristic manner. The major interaction with the surface in this case is adsorption of individual elements (especially the metallic elements). The alkali elements (like sodium or cesium) do not adsorb on surfaces very strongly, the alkaline earth elements adsorb in larger extent, and the rare earth elements to a greater extent than the alkaline earths. The degree of adsorption is in order of the charge on the ions from +1, +2, to +3. The equilibrium amount of each adsorbed depends on the amount of each present initially in the drop. The amount directly adsorbed by the surface cannot be removed without either removing some of the surface, or without imparting a great deal of energy to the surface layer either by physical or chemical means. Water washing, for example, simply washes away the equilibrium amount left in the salt layers above the surface.

The Freundlich adsorption isotherm can be adapted to describe the adsorption process and subsequent washing of the surface. For a given element, it is—

$$F_j = R_j/I = a_j I^{n_j - 1} \quad (1)$$

in which I is the initial level (later defined in total r/hr of which element j contributes a stated fraction at the time, t, after detonation; R_j is the amount left after washing (i. e., the amount adsorbed); and a_j and n_j are the impirical adsorption constants. The fraction remaining is—

$$R_j = a_j I^{n_j} \quad (2)$$

equations (1) and (2) apply either to a single drop or to the whole surface if at least a single layer of drops has been deposited. The intermediate situation is for rather low contamination levels and requires rather complicated equations; therefore, the following treatment will assume a serious contamination of the surface as the lower initial level of interest. For chemisorption which obeys equation 2, n_f is less than 1 so that the fraction remaining decreases with decreasing initial level.

In this type of fallout, another interaction can take place within the water drop either during its fall to earth or after it lands. Likely bomb and target structural materials will include fairly large amounts of iron, aluminum, etc. These materials will be oxidized and will form hydrous precipitates in the water drops. Many of the radioactive atoms will adsorb or mix with these precipitates. When these are present, a three-way interaction occurs on the surface rather than just the one previously described. Simple washing methods will dissolve only a small amount of the precipitates once they are dried on the surface, and during the process an equivalent amount of the radioactive elements will be released.

A rigorous mathematical solution of all the physical chemistry equations and material balance equation for the three-way process cannot be made; however, suitable approximations can be made for simple water washing of the surface. The fraction remaining for this case is—

$$F_i = a_i I^r j + \frac{I}{k_i + I} \tag{3}$$

in which, for a given element,

$$K_i = dK_c V / q_r(t) \tag{4}$$

in which (1) d is the density of the hydrous oxides.

(2) V is the equivalent initial volume of the fallout (before evaporation begins), deposited per unit area of surface.

(3) K_c is the equilibrium constant for the distribution of the element between the liquid and solid phase,

and (4) $q_r(t)$ is the ratio of the weight of the bomb (and target, as Al, Fe, etc.) per unit area to the amount of radioactive elements present; $q_r(t)$ therefore depends on the yield and is given by

$$q_r(t) = \frac{kM_B Y(t)}{bW[A_{FP}(t) + a_I(t)]} \tag{5}$$

in which (1) M_B is the total mass of bomb (and target material thrown up),

(2) $Y(t)$ is the ratio of r/hr to d/m per unit area at time, t, after detonation and depends on the photon energy spectrum,

(3) W is the total yield of the weapon,

(4) b is the ratio of fission to total yield,

(5) $a_{FP}(t)$ is the activity of the FP from 10^6 fissions in d/m at time, t.

(6) $A_I(t)$ is the sum of the induced activities for 10^6 fisisons in d/m at time t.

and (7) K is a constant relating the fission yield and the number of fissions in appropriate units.

The various quantities illustrate the kind of weapon or detonation parameters which are related to the chemical interaction at a surface many miles away from the attack as well as the information required to properly interpret decontamination test experimental results.

LAND FALLOUT

Land fallout will consist of soil material, bomb structural and target materials, and radioactive products. The bulk of the fallout material from a surface detonation will be soil particles in which the radioactive elements are fixed. Therefore a decontamination procedure which moves the particles from a surface also moves the radioactive material.

In this case, the fallout particles maintain their size all through the process and since their density is high, the majority fall more vertically than the sea-water fallout (in same wind speed), and, where the initial deposits are high enough to be of concern the horizontal surfaces will be more highly contaminated than vertical ones.

For surfaces which are contaminated with more than a single layer of particles, only the bottom layer actually "contaminates" the surface: Most decontamination methods are capable of removing all the superficial layers of particles. If a method removes all but the surface layer (or, all layers and all particles greater than a given size in contact with the surface), then the amount left after decontamination is a constant, independent of initial deposit. For this process, the fraction of the mass of fallout remaining is

$$F_m = \frac{R_M}{y} \tag{6}$$

in which R_M is a constant dependent on the particle size and method of decontamination and y is the initial deposit in mass of (solid) fallout per unit area. The mass representation is used here to emphasize the fact the soil particles and not radioactive atoms are being acted upon during the contamination and decontamination process.

For surfaces which are contaminated with less than a single layer of particle, the above mechanism of removal is postulated for the fraction of the area which is covered with particles. Since the landing of a given particle on a given spot on a surface is a statistical process with the probability of the next particle landing on a "clean" spot being proportional to the clean area, the fraction of area covered at any time (say, at the end of fallout) will be

$$f = l - e^{-\alpha y} \tag{7}$$

in which α is a constant called the spreading coefficient; its value depends on the average particle size and the roughness of the surface. Thus the general equation for levels of initial deposit is

$$F_m = \frac{R_M(1-e^{-\alpha y})}{y} \tag{8}$$

The fraction, f or $(l-e\lambda^y)$, becomes one for a single layer of particles at which level equation 8 reduces to equation 6.

Equation 8 is converted to radiation intensities by means of a quantity called the mass contour ratio $M\lambda rt$), in units of the ratio mass of fallout per unit area to r/hr. Briefly, the mass contour ratio is given by

$$M_r\lambda t) = \frac{f'k'A\lambda W^{(n-1)}}{bY(t)[a_{FP}(t) + a_I t]} \tag{9}$$

in which (see equation 5)

(1) $A\lambda W^n$ is the scaling relation for the mass of material thrown out of the crater,
(2) n is an empirical constant,
(3) $A\lambda$ is an empirical parameter depending on the scaled height or depth of burst, λ
(4) λ is defined as the height or depth of burst in feet divided by the cube root of the yield in pounds of TNT,
(5) k' is a converting yield to fissions and other units, and
(6) f' is the fraction of the crater mass which mixes with the radioactive elements.

In radiation intensities, equation 8 is

$$F_r = \frac{R_M(1-e^{-\alpha M_r(t)I_r})}{M_r(t)I_r} \tag{10}$$

Harbor fallout

Harbor fallout can be either like sea-water fallout or like land fallout or a mixture of any combination of the two. A low yield burst on the surface of a deep harbor would give a sea-water fallout; a high yield detonation on the surface of a shallow harbor will produce a land fallout.

For the intermediate cases, the fallout will consist of sea water, harbor bottom (soil), bomb structural and target materials, and radioactive elements. The composition of fallout from harbor detonations can be described by their solid to liquid ratio, β.

Experimental data indicate that the additional phase (soil) to the seawater fallout induces only a negligible added interaction for most radionuclides and thus the total effect can be treated as a simple mixture of sea-water and land fallout. Where this is so a single representation can be made for all possible

types of fallout. The general equation, in terms of the ratiation intensity at H+1 hr, is

$$F_r(f)=\left[\exp-\frac{\lambda\beta}{1+\beta}M_r(1)I_r(1)\right]\sum_{j=1}^{j=n}P_j(t)F_j(t)+\frac{R_M}{M_r(1)_rI(1)}\left[1-\exp-\frac{\lambda\beta}{1+\beta}M_r(1)I_r(1)\right] \quad (11)$$

$$F_j(t)=a_{jr}(t)[I_r(1)]^{n_j(t)-1}+\frac{I_r(1)}{K_{jr}(1,t)+I_r(1)} \quad (12)$$

in which $P_j(t)$ is the fraction of the radiation intensity contributed by the radionuclides of element j; the sub r indicates an evaluation in terms of r/hr, the (1) indicates an evaluation in terms of r/hr at 1 hr after burst, and (t) indicates the parameter depends upon the time the surface has been contaminated—i. e. requires evaluation for the time, t, after burst when the decontamination is carried out.

The results of some laboratory scale data from synthetic fallout together with constants for a hypothetical nuclear bomb were used to evaluate other empirical constants. These were used to compute the final levels for a decontamination at 7 days after burst for initial levels ranging from 10 to 10,000 r/hr at 1 hr. The curves for a β of zero (sea-water fallout) to a $\beta \geqslant 1{,}000$ (land fallout) at selected intervals are plotted in figure 1.

At the present time, there is not enough data available to determine a similar three dimensional decontamination surface (or even a partial surface) for any available reclamation method-surface combination. Since large scale reclamations are expensive and difficult, the preferable experimental technique would be to investigate the nature of the decontamination surface for a series of method-surface combinations by use of small-scale experiments in the laboratory and to check these with a few carefully chosen large-scale experiments with sufficient correlation experiments to make proper adjustment of the equation parameters.

CONTAMINABILITY OF TARGETS

The vulnerability of targets to contamination by fallout must consider three parameters:

(*a*) Does the fallout contact the surface?
(*b*) Once in contact, does it remain on the surface?
(*c*) How tenaciously is it attached, i. e., how easy is it to remove?

Such information is important for:

(*a*) Predictions of the relative radiological hazard within the target complex so as to exploit this variability operationally.

(*b*) Predictions of the over-all vulnerability of structures that incorporate shielding.

(*c*) Design and planning criteria for recovery procedures.

(*d*) Design criteria to provide minimum vulnerability of targets.

Factors influencing the contaminability of targets are:

(*a*) Gross geometry and configuration which determine the airflow patterns around the target and/or influence the "drainage" of material from the target surfaces.

(*b*) Physical and chemical characteristics of surface materials, i. e., roughness, porosity, adsorbability, chemical reactivity, etc., which influence the "entrapment" of fallout and ease of loosening, removal, and transport of contaminant by decontamination processes and/or natural weathering.

(*c*) Meteorological conditions which determine the initial distribution of fallout, and its resuspension and/or redistribution.

(*d*) The physical and chemical characteristics of the fallout, i. e., type (deep water, harbor, or dry land), chemical state, particle size, density, etc., which influence the "flight" characteristics, the impact and retention characteristics and the tenacity with which it is held to the surface.

Various laboratory and field tests have been made of the contaminability of surface materials as related to fallout characteristics and angle of inclina-

tion.[1,2,3,4] The contaminability of targets as related to micrometeorology and geometry have not been studied directly, but some information has been derived from experiments with other objectives.[5] As an example, a ship was exposed to fallout from a deep-water detonation.[6,7] The fallout arrived in a 15- to 20-knot wind on the starboard beam.

The following results were obtained:

(*a*) The contamination level (240 readings) on horizontal surfaces varied from 16 percent to 400 percent of the average, i. e., the largest was 25 times higher than the lowest.

(*b*) The gamma radiation level at 3 feet above the deck varied by a factor of 10.

(*c*) The average contamination level for vertical surfaces varied from the average horizontal reading as follows:

1. Forward part of the ship: 40 percent of horizontal average.
2. Aft part of the ship: 20 percent of horizontal average.
3. Lee side: 10 percent of horizontal average.
4. Windward side: approximately equal to horizontal average.

(*d*) Test panels at the stern of the ship had an average contamination level on vertical surfaces three times higher than levels on horizontal surfaces.[8]

Such data cannot be extrapolated or used for predictions without a better understanding of all of the factors involved.

In another example, small buildings and panels of typical building materials were exposed to fallout from land detonations.[4] The contamination levels on typical roofing materials was as much as 300 times higher than that on typical wall panels; or a vertical to horizontal relationship of about 0.3 percent. For panels of the same material, vertical readings were about 10 percent of the horizontal.

The two examples indicate considerable difference in the vertical to horizontal relationships. The characteristics of the fallout appear to have had a considerable influence on this distribution. For instance, the land detonation normally produces a "dry" fallout composed primarily of material from the crater. One can expect masses of 3 to 300 grams of material per square foot to be associated with significant radiation levels at early times. The fallout being a dry powder has little tendency to stick on vertical surfaces.

The fallout from deep-water detonations is largely composed of sea water salts. However, much of the water may evaporate, leaving particles that are damp, semicrystalline masses of a sticky nature. They are capable of sticking to vertical surfaces.

As indicated very little is known of the overall problem of contaminability. It is obvious, however, that two assumptions often made, i. e., ((1) that the fallout is distributed homogeneously on a uniform infinite plane, and (2) that vertical surfaces are not appreciably contaminated) are subject to serious limitations. The ability of a tactical force and/or a civilian population to exploit the variability of the fallout pattern depends upon knowledge we do not have on contaminability.

The contaminability of personnel exposed to the fallout event or working and living in contaminated environments is largely unknown. A study[9] indicating the significance of beta contact hazard to personnel and a requirement for the mass decontamination of personnel, emphasizes the need for additional contaminability information.

Cost of Reclamation

Considerable data has been collected regarding the effectiveness of reclamation of targets contaminated by local fallout. The feasibility of applying these methods depends upon the following parameters:

(a) The time required to perform the reclamation must be short enough to make an appreciable saving in radiological exposure to mission personnel,

(b) The radiation exposure to reclamation personnel must be justified by the saving in exposure of mission personnel,

(c) The effort (manpower) and logistics required to reclaim the target must be compatible with the total effort available.

Thus, the cost of reclamation as measured in operating time, effort, radiation exposure, equipment, and supplies is an important determination.

It is impossible to generalize on these quantities for they are influenced by many factors.

The type of fallout, whether it be from a deep water, harbor or land detonation, influences the rate and/or method of decontamination. A deepwater-type fallout can be removed only to an extent of about 60 percent for a firehosing, scrubbing operation on ships,[1] the rate being about 40 square feet per minute. The same decontamination procedure at 6 times the rate of operation on a paved area contaminated by dry-land-type fallout will yield a removal of about 98 percent.[2] To achieve an equivalent removal on the ship, a surface removal technique would be required. Typical rates of operation are about 20 feet per minute for paint stripping[3] and about 7 feet per minute for removing a ⅛-inch thick layer of wood from the flight deck.[4]

The amount (or mass) of fallout on a surface influences the rate, particularly for harbor and dry-type fallout that must be transported over horizontal surfces for considerable distances. The following table shows an example of how the rate decreases with increasing masses of dry fallout for motorized flushing.[2]

Dry fallout gm/ft:[2]	*Motorized flushing rate, ft.²/min.*
10	670
33	650
100	580
330	300

The mass of fallout has no effect on the rate of operation for surface removal or earth moving techniques.

The rate of operation is influence by the surface characteristics of the target, rough surfaces, e. g., wood shingles, requiring longer time than smooth, e. g., metal surfaces. The following table is an example of the influence of surface roughness on rate of operation:[2]

Firehosing of dry contaminant

Material	Effectiveness (percent removed)	Rate (ft²/min/hose)
Corrugated metal	97	65
Composition shingles	95	50
Wood shingles	89	35

The rate of reclamation by earth moving is influenced by soil characteristics. Standard earth moving practice has developed considerable information on this subject.

[1] AFSWP, ITR 1323, preliminary report, Operation Redwing, project 2.9, Standard Recovery Procedure for Tactical Decontamination of Ships. Confidential.

[2] Field Evaluation of Cost and Effectiveness of Basic Decontamination Procedures for Land Target Components, Sartor, J. D., Curtis, H. B., etc., USNRDL–TR in preparation. Unclassified.

[3] Rates approaching 50 square feet per minute are possible if removal of only the surface layer of paint gives the required reduction in radiation intensity.

[4] Proof Testing of AW Ship Countermeasures, Operation Castle, project 6.4 WT-927, Molumphy, Bigger. Confidential.

The degree of mechanization obviously influences rate of operation. The following example compares firehosing rate with that of motor flushing for harbor-type fallout. Also shown are the influence of mechanization on effort and radiation exposure.[2, 5]

Criteria for comparison	Actual performance or cost		
	Firehosing	Motorized flushing	Relative cost FH/MF
1. Operating rate per unit, hr/10^6 ft^2	222	30	7.4
2. Personnel required per unit	5½	2	2.75
3. Effort (direct labor), man-hr/10^6 ft^2	1,210	60	20.0
4. Radiation shielding factor	1.0	0.5	2.0
5. Relative cost in radiation dose	1,210	30	40.0

Target complexity obviously influences rate of operation. For optimum performance, spacings between target components must be large enough to permit mechanized equipment to be used.

A simplified example will help indicate the time, manpower, and basic supplies required for recovery of a target complex. The following criteria are assumed:

(*a*) Target: City of San Francisco.
(*b*) Fallout: Harbor-type at 33 gms/ft^2.
(*c*) Area to be recovered: About 25 square miles consisting of—
1. All paved areas.
2. All industrial and commercial areas and buildings.
3. 50 percent of the park areas.
4. 10 percent of the residential areas and buildings.

(*d*) Methods: Firehosing and earth moving.

The following table indicates an estimate[5] of the cost of reclaiming these critical areas:

Cost of decontaminating critical areas of San Francisco through use of available firefighting and earth moving equipment for removing slurry contaminant

	Firehosing			Earth moving, land areas	Grand total
	Roofs	Paved surfaces	Subtotal		
1. Time to complete decontamination (24-hour days)	16.8	11.7	28.5	13	----------
2. Direct labor (number of men)	----------	----------	4,000	2,800	6,800
3. Total labor, direct and support (number of men)	----------	----------	6,000	4,900	10,900
4. Total effort (8-hour man-days)	101×10^3	70×10^3	171×10^3	64×10^3	235×10^3
5. Labor cost at $10 per man-day	----------	----------	1.71×10^6	0.64×10^6	2.35×10^6
6. Water required for decontamination (gallons)	362×10^6	314×10^6	676×10^6	----------	----------
7. Fuel required (gallons):					
(*a*) Gasoline	145,000	101,000	246,000	95,000	341,000
(*b*) Diesel fuel	----------	----------	----------	195,000	195,000

As can be seen, the reclamation is feasible in what appears to be a reasonable time. The amount of equipment required is within the capability of existing sources in San Francisco. The manpower is not too excessive considering the numbers of people available. The water requirements are within the capability of the normal supply. Fuel consumption is less than normal daily requirements. The greatest problem would undoubtedly be that of organizing, training, supervising, and controlling 11,000 men.

Automatic decontamination devices such as the washdown system have, as an important advantage, the capability of reclamation at very early times with no expenditure of manpower or radiation exposure. They can be extremely effective (i. e., removal of 90–95 percent) even on sea-water-fallout.[4] However, they do require expenditure of funds before the war begins.

[5] Engineering Approach to Radiological Decontamination, Hawkins, M. B. (Paper to be given ASME semiannual meeting, San Francisco, June 1957.) Unclassified.

The Need for a National Program in Nuclear Countermeasures

The full exploitation of nuclear weapons and nuclear power requires that full preventive measures be employed at all times to keep potential exposure below hazardous levels, *and* that the capability of reclamation after any nuclear mishap be high.

The current policies of the AEC and DOD, backed by the very competent Health and Safety Division in the AEC installations, have provided a generally satisfactory national program based on *preventive* and control measures. No similar program exists to fulfill the reclamation requirement, or to prepare the way for successfully coping with a general increase of radioactive background above that imposed from natural sources. Such an increase is inevitable—both on a general scale and on a more limited scale. The general buildup is predominantly related to weapon detonations. The more limited scale is confined to such areas as the exclusion zones of the Nevada test site, the Reactor Test Station, Arco, Idaho, etc. From the other extreme, there is an increasing demand to establish contamination specifications for the general release of previously contaminated equipment into the established industrial channels.

It is proposed that a positive national program of nuclear countermeasures development be undertaken to add preprotection and reclamation capability to the established preventive measures.

Four completely different types of end-use application are apparent:

(1) Increasing the nuclear resistance of military operating forces in the field.

(2) Continental defense of the United States in time of total nuclear war.

(3) Reclamation from a nuclear mishap in times of peace.

(4) Adaptation of the established economic system to absorb the applications of nuclear energy that are already developed, or under development.

The four applications are common in that one is faced with the impact of radiation and radioactivity on the civilian and/or noncombatant society. The control techniques used during the research, development, and production phases are no longer sufficient since these techniques rely solely on control and preventive measures.

The four applications differ in that the criteria relating the nuclear or radiological environment to the permissible dose or acceptable hazard are not completely common.

However, much of the research and development up to the point of final application is interchangeable. A unified research and development program should have a large payoff value on all four fronts. It also appears that the DOD, AEC, FCDA, and possibly the PHS all have a vital interest in such a unified program.

Summary of Nuclear Weapon Countermeasure System Development Program Proposal (Special Test Program Component)

This memorandum summarizes the proposals advanced by the United States Naval Radiological Defense Laboratory as representing the fastest and most economical way of developing a national capability in nuclear weapon countermeasures. This proposal has formed the basis of discussions with Mr. R. L. Corsbie and Dr. A. W. Bellamy, representing the Atomic Energy Commission, concerning the manner in which nuclear weapon tests could be more profitably exploited. The same proposal has been discussed with the FCDA Planning Office, but has not been formally developed.

To insure the greatest level of national readiness in minimum time, the nuclear weapon countermeasure system must be developed with the same care that has gone into the development of the offensive weapon systems. It is proposed that a nuclear weapon countermeasure system development program be established, and that a *proof test* of the proposed system be made at a special test to be conducted in accordance with the attached schedule. This test will:

(1) Proof test proposed standard shelter designs.

(2) Proof test proposed rapid reclamation systems.

(3) Establish an experimental basis for determining criteria required to achieve final recovery.

Such a program cannot succeed if projects are submitted by invitation to all agencies that may have an interest in the subject. The test projects must be carefully planned to proof test an integrated system and must carry through all three time phases: emergency, operational recovery, and final recovery. The United States Naval Radiological Defense Laboratory believes it has the competence to develop such an integrated system. Adequate criteria exist to justify an operational development program of both emergency and operational recovery phases. Adequate criteria do *not* exist to establish feasible systems for the final recovery phase. Therefore, this test must be used to aid in the experimental determination of such criteria including food management and agricultural reclamation. The capability of existing instrumentation and doctrine to provide the required radiation and operational control data will be able to be determined realistically.

This program is only one part of the required national weapon countermeasure program. However, it provides the essential base against which real progress can be evaluated.

The proposals submitted to Mr. Corsbie for Operation Plumbbob are developmental projects covering some aspects of the emergency and operational recovery plans.

Outline of Essential Timetable

R&D program leading to selection of system components and establishment of necessary projects	Test date minus 3 years	
	Test date minus 2 years	Site selection and program scope completed
	Test date minus 1 year	Submission of complete test program plan
Construction, equipment procurement, training		
	TEST DATE	
Operational recovery begins Shelters, situation appraisal, etc.		Emergency phase complete
Transition to final recovery begins	Test date plus 6 months	Final report on emergency phase program
	Test date plus 9 months	Operational recovery complete
	Test date plus 18 months	Final report on operational recovery phase program
Experimental program to measure incorporation of critical elements into the environment and their uptake into animals. Agricultural reclamation experiments.	Test date plus 3 to 5 years	

Evaluation of the state of knowledge relating to radiological countermeasures development[1]

	Continental defense	Peacetime application
Transport mechanism	A	C
Nuclear and chemical properties	A	B
Contamination-decontamination phenomena	C	C
Reclamation methods	B	C
Component development	C	C
Shielding and terrain effects	B	B
Shelter development	B+	(2)
Final recovery	C	C
Systems development and analysis	B	B

[1] This table was developed by Dr. Paul C. Tompkins, USNRDL, Mr. R. Corsbie, and Mr. J. Deal, DBM of the AEC, to guide the development of projects to improve the nuclear weapons defense capability of the Atomic Energy Commission. It has been examined by the technical staff of the USNRDL and is considered to be a fair evaluation of the current state of real knowledge.

[2] Not applicable.

NOTE.—State of knowledge and effectiveness of application based on the ability to apply determinable numbers in a wide range of actual cases:
A—Adequate for practical applications
B—Inadequate for practical applications
C—Little known

STATEMENT BY LEROY H. CLEM[1] OF THE AIR WEATHER SERVICE ON FALLOUT PREDICTION

The prediction of radioactive fallout is a combined meteorological and radiochemical problem. The mission of the Air Weather Service does not include any treatment of the radiochemical portion of the problem but is confined to the indication under emergency wartime conditions of the effect of only the meteorological variables on the transport of radioactive debris during its fall back to earth within a few hundred miles of the site of a nuclear detonation. To accomplish this mission requires accepting certain rather gross assumptions about such nonmeteorological variables as the initial distribution of contaminated particles in the stabilized cloud and the particle fall rates. Thus, given these gross assumptions, the only additional factors with which the Air Weather Service forecasters are concerned are the time and location of the occurrence of a nuclear detonation and the best estimate of the wind field through which the radioactive debris will fall.

The idealized meterological solution to this problem involves the computation of a whole family of three-dimensional trajectories starting from various levels of the atomic cloud. By considering changing wind conditions, these trajectories represent the fall paths of a variety of particles (of differing size and shape) which were present at the various levels in the cloud when it stopped rising. Such a solution is beyond the present state of the science of meterology. Therefore, the Air Weather Service, as well as other agencies, had to make certain simplifying meterological assumptions in order to be able to handle the forecast problem.

The generally accepted method is based on the following main assumptions:

(*a*) The winds at selected levels in the middle of layers (e. g., 10,000 feet thick) are representative of the windflow that would effect the drift of the particles while they are falling through that layer.

---

[1] Bachelor of science degree, Brown University; certificate for graduate meteorological engineering, New York University; master of science degree in meteorology, Massachusetts Institute of Technology; 13 years of professional experience in meteorology; during World War II served as an aerological officer in the Navy; several years experience with the U. S. Weather Bureau; serves as the expert on fallout-prediction problems, high level wind problems and forecast capabilities. Assigned to the Technical Service Branch, Technical Requirements and Services Division of Scientific Services of Headquarters, Air Weather Service. (Submitted by Department of Defense.)

(*b*) The wind sounding (observed or forecast) for the upper-level winds applicable at the point of detonation is representative of the windflow throughout the course of the ensuing fallout.

It is believed that assumption (*a*) does not introduce much error; however, assumption (*b*) is both the heart of the technique and the most questionable of these two assumptions. Although experience has shown that persistence forecasts (implied in (*b*)) of upper-level winds are equal to or better than other available forecast methods for the first few hours, variability of the wind, when coupled with the inaccuracies of wind observations and forecasts, introduce sizable errors in the method. The average error in the resultant 6-hour forecast fallout plot derived from this method is of the order of ± 10 to ± 30 degrees in direction and 30 to 40 percent in distance. The forecast errors involving fallout coming from the higher levels of radioactive clouds formed by large weapons are relatively smaller than those for fallout from the lower levels of the clouds.

However (even in view of these inaccuracies), by using the stated meteorological assumptions, it is possible to compute the most probable geographical area that may be contaminated by radioactive fallout following a surface or near-surface burst of a nuclear weapon. There are more sophisticated and time-consuming computational techniques available, involving more complex assumtions than (*b*) which are supposed to take care of some of the variability of the wind. However, evaluation tests have indicated that the slight decrease in the resultant errors from using these more complex methods does not justify the extra computational time and effort involved. The Air Weather Service method, based on a very simple and versatile 6-hour wind-vector technique, is equally useful in this country as well as overseas and can be evaluated for any desired area on the earth's surface or at altitudes normally used by aircraft. This method consists of adding the wind vectors from the layers through which the particle will fall and then (with an assumed fall-rate) a fallout plot is developed from this. This results in a time-space plot which delineates the areas which may receive fallout and the expected time of occurence. It should be noted that no attempt is made in this method to forecast levels of radiation intensities, relative or absolute.

Although this method for forecasting the close-in areas which are expected to be contaminated by falling radioactive debris does not achieve the accuracy and precision ideally desired (because of many unresolved factors, some of which are nonmeteorological), its accuracy (± 10 to ± 30 degrees in direction and 30 to 40 percent in distance from ground zero) is in line with the current state of the science. There are no techniques available today which can provide more than very generalized answers in a forecast situation involving large weapons.

STATEMENT BY COL. B. G. HOLZMAN[1] AND COL. NORAIR M. LULEJIAN,[2] AIR FORCE RESEARCH AND DEVELOPMENT COMMAND

Question. How does your organization predict fallout, given weapon yield, height of burst, type of terrain, and meteorological conditions? How reliable do you feel these forecasts are?

Footnote continued on following page.

Answer. The Air Force Research and Development Command has developed a simple method to predict the general area within which fallout may occur. An attempt was made for several years to develop a more rigorous treatment of the fallout problem; however, this approach was abandoned because of the inherent time and space variability of the atmospheric winds which introduces large errors in all fallout predictions. It is the opinion of Air Force Research and Development Command that in view of the large errors introduced by the variability of the winds, it is pointless to attempt a precise model of the radioactive distribution in the atomic cloud. The fallout pattern influenced by different types of terrain are completely masked by the very large errors introduced because of variability of the winds. Experience during past atomic-test operations has verified the fact that even when zero-hour-measured winds were used, thus eliminating all wind-forecast errors, the actual fallout never occurred in the exact region indicated by the observed winds. There was always a displacement varying up to 45° of the actual fallout from its calculated position. The reason for this is simple. The observed winds are valid over the target area for a relatively short time. Fallout may reach a distance of 150–250 miles downwind and it may take 6–18 hours for the local fallout to be completely deposited on the ground. During this 6–18 hours the winds change both in direction and in speed. There is not only this time variation, but also the space variation. In other words, the winds aloft over ground zero are not necessarily the same as winds 150 miles downwind. Furthermore, the method of measuring winds by the use of balloons introduces another serious error because of the inability to specify the true wind profile directly over ground zero.

It is questionable whether the time and space variability of the winds could be forecast with an accuracy exceeding ±15° in the direction of the winds. An error of 15° would spell the difference between an airbase or a city receiving either no radiation at all or possibly lethal concentrations of radiation from the local fallout of a single weapon.

We have considered fallout from the offensive and defensive points of view. For defensive purposes before we can make any reasonable estimates of the local fallout plot we need to know the total yield as well as the fission yield of the weapons, height of burst, and coordinates of ground zero. Even with all this information it will be impossible to delineate the fallout pattern with sufficient accuracy to predict whether a given military installation downwind of ground zero would receive no, little, or lethal concentrations of radiation. For offensive use a further complexity is introduced because most probably very little if any reliable meteorological information will be available over enemy territory. Therefore, in spite of our knowledge of the yield, height of burst, and ground zero on bombs, the fallout pattern over enemy territory would be equally if not more difficult to predict.

When many multimegaton weapons are exploded, the calculation of reasonably accurate fallout patterns becomes even more difficult. The validity of the requirement for ascertaining fallout patterns under these conditions becomes even more questionable because lethal contamination will occur over large overlapping areas regardless of the meteorology.

However, the above should not be construed to mean that we are unable to make generally correct predictions; for instance, as to what countries or large areas shall lie inside or outside the dangerous part of fallout patterns from distant bursts. A choice of burst height that prevents the fireball from touching the earth, essentially eliminates local fallout.

---

2 years; entered military service in September 1942, and enrolled as an air cadet in meteorology in January 1943 at Grand Rapids, Mich.; received his commission as second lieutenant in September 1943; returned from overseas early in 1946 and served with Headquarters Air Weather Service until September 1946, after which time he was transferred to Headquarters, USAF, in the Pentagon. He left Headquarters, USAF, to enter a 3-year course in radiological engineering in September 1948; assigned to Headquarters, ARDC, in Baltimore since June of 1952. He is Chief of the Nuclear Applications Division of the Directorate of Air Weapons. (Submitted by Department of Defense.)

STATEMENT BY DR. DONALD M. SWINGLE[8] OF THE ARMY SIGNAL CORPS, EVANS, S. C., LABORATORY, FOR SUBMISSION TO THE JOINT COMMITTEE ON ATOMIC ENERGY

Question. How does your organization predict fallout, given the weapon yield, height of burst, type of terrain, and meteorological conditions? How reliable do you feel these forecasts are?

Answer. 1. The principles of fallout prediction used in the Signal Corps method are outlined below:

(*a*) The prediction procedure described assumes a surface burst of a nuclear weapon. Given the weapon yield, the dimensions of the cloud are estimated from a survey of previous test data. (See discussion below.)

(*b*) The cloud is split into layers, on the basis of available data on particle-size distribution, and the particle sizes in each layer are considered.

(*c*) Where each particle size in each part of the cloud will land is determined by trigonometry, considering rate of fall and the effect of wind. It is assumed that the latest available wind data is representative.

(*d*) Then the ground position of arriving fallout is plotted and overlapping contours are added together.

(*e*) A meteorological contour analysis of the resulting pattern is made and this is analyzed for dose-rate information.

(*f*) The time of arrival on the ground of each particle size for each original slice is calculated and analyzed for *time of arrival* and *time of ending*, if wanted, of fallout material.

(*g*) From consideration of the time of arrival and dose rate, the *total dose* for 48 hours is approximated.

In the above procedure, terrain has not been specifically considered.

2. The effective radiological activity predicted would be affected by the estimated height of the cloud. The ratio of fission to total yield of the burst will affect the estimated dose rates and the total dose.

3. If the height of the cloud is known, the height to which wind data is required is immediately known. Assuming the height of the cloud is not known, the height and diameter may be estimated from the meteorological conditions. The criterion for estimating the cloud height is the height of the tropopause. This is accomplished by adjusting the basic pattern design for location of burst and for the season.

4. The accuracy of fallout prediction is directly related to the accuracy of the basic information. The degree of reliability of the several factors and the variation of wind with time and space prohibit exacting prediction. The Signal Corps is studying the question of attainable accuracy. But data for vertification of pattern design is limited. Considering the factors outlined above and when the fission to total yield is known, it is hoped to attain fallout prediction within a factor of 2 for points within contour lines of 100 roentgens per hour or greater.

5. The details of a Signal Corps draft method of fallout prediction are being reviewed and the method is being modified. Consideration is being given to the effect of time and space variations of the wind. The present method utilizes an effective wind consideration at the point of burst to be applied throughout the pattern computation.

TECHNICAL PRESENTATION FOR THE JOINT COMMITTEE ON ATOMIC ENERGY HEARINGS ON THE SUBJECT, THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN, MAY 27–29 AND JUNE 3–7, 1957

Specifically on—

Topic VI. Atmospheric Transport, Storage, and Removal of Particulate Radioactivity
Topic VII. Local Fallout
Topic VIII. Delayed Fallout

Submitted by James G. Terrill, Jr.,[a] Chief, Radiological Health Program, Division of Sanitary Engineering Service, Public Health Service, United States Department of Health, Education, and Welfare

VI. ATMOSPHERIC TRANSPORT, STORAGE, AND REMOVAL OF PARTICULATE RADIOACTIVITY

Public Health Service fallout activities have emphasized the collection of data on the actual exposure of people which data can be used to modify operational procedures to reduce the exposures and to serve as a basis for studying possible chronic radiation effects.

B. Local fallout

Local fallout is initially of concern as an acute external gamma or beta irradiation hazard. For this reason our off-site radiological safety operations in Nevada and in the Pacific are based on external gamma readings obtained with portable survey instruments. This system of operation is based on the assumption that beta concentrations during this period are substantially in proportion to the gamma intensities. This assumption has been confirmed, in general, by results of beta measurements of air samples collected during the fallout periods in Nevada. Local fallout may, and has become of concern as an internal beta emitter after its decay to a level at which the gamma irradiation is no longer of concern from the standpoint of acute effects. Up to this time the Service has not attempted to measure alpha concentrations in local (or delayed) fallout although the amounts are presumed to be low.

A report of local fallout sufficiently detailed to be used for public health purposes is the Report of Off-Site Radiological Safety Activities from Operation Teapot conducted at the Nevada test site in the spring of 1955, prepared jointly by the Las Vegas Branch Office of the Atomic Energy Commission and the Public Health Service.[1] Comments concerning the predictability of local fallout and observed patterns of local fallout will be based on this report.

The Teapot report outlines Public Health Service responsibilities and the supporting services, including air support, provided by other agencies.

Data gathered during this operation make it possible to:

1. Compare predicted fallout with the fallout as it actually occurred;
2. Compare the radioactive cloud path with the deposition of activity on the ground; and
3. Report on observed patterns of local fallout in terms of external gamma radiation.

1. The predictability of local fallout.—Fourteen devices were detonated during Operation Teapot. In reviewing the data on predicted and measured fallout from these detonations, it was found that in 5 cases the prediction is in substantial agreement with measured fallout, while in 6 cases the actual deposition of fallout was significantly at variance with the prediction. Three devices were air detonated and no fallout prediction per se was used. Chart I illustrates a case where the fallout prediction compares favorably with the fallout which actually occurred. Chart II shows a typical deviation from the predicted fallout, while chart III shows a major deviation from the prediction.[1]

[a] Graduated from the University of Cincinnati in 1937 with a degree in civil engineering. Studied public health engineering at the Massachusetts Institute of Technology Graduate School from 1938–41. Since 1941 he has been active in the Public Health Service. Participated in the first Bikini tests. During the period 1948–51 he studied radiological defense under the sponsorship of the Armed Forces special weapons project at the U. S. Navy Postgraduate School and the University of California. He participated in and directed the Public Health Service activities related to the Nevada and Pacific test operations during 1953–57. Active in radiological committees of the American Society of Civil Engineers and the American Public Health Association. Member of the National Committee on Radiation Protection and the Nuclear Standards Board of the American Standards Association. Presently chief of the radiological health program, Division of Sanitary Engineering Services, Public Health Service. (Submitted by witness.)

[1] Report of Off-Site Radiological Safety Activities, Operation Teapot, Nevada test site, spring 1955.

It should be emphasized that these data are for gamma radiation only and represent only particulate material fallen from the cloud. They do not take into account isotopes, such as iodine, that may be in a gaseous form and may not follow the fallout pattern. We plan to study this as well as other problems related to fallout exposure during and following Operation Plumbbob as a part of our off-site operation carried out under agreement with Albuquerque Operations Office of AEC. This work also has the concurrence of the Division of Biology and Medicine of AEC.

CHART 1

FALLOUT PATTERNS

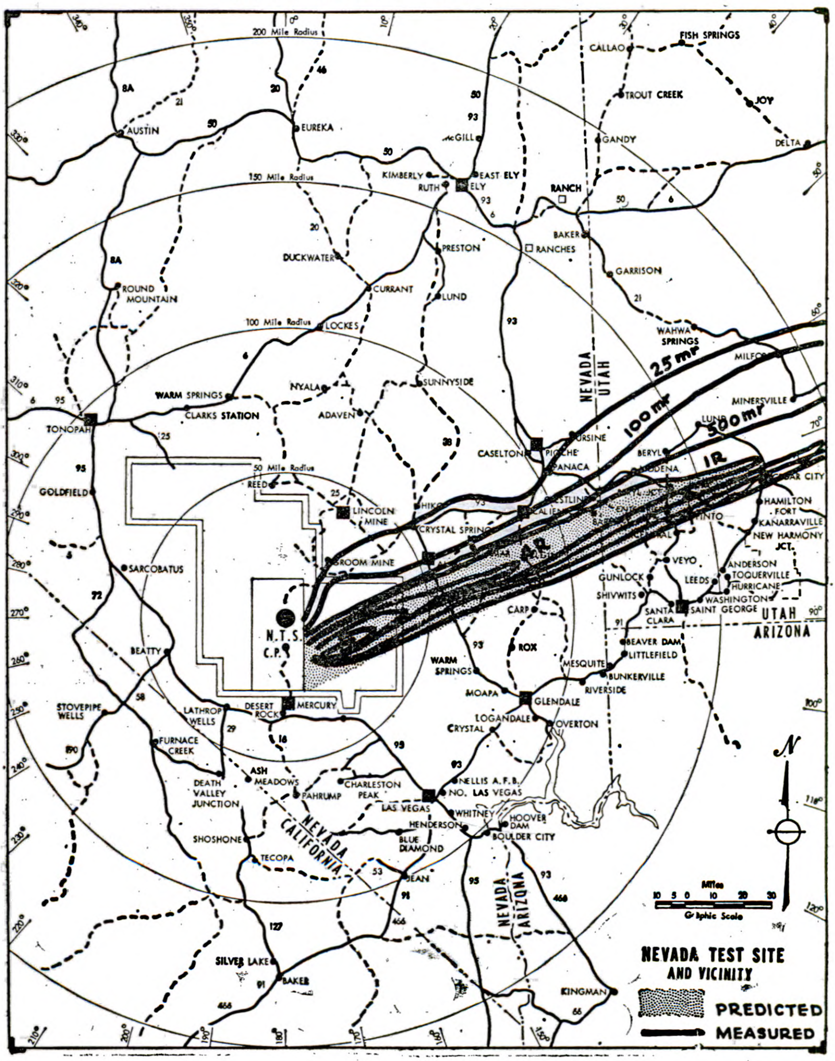

CHART 2

FALLOUT PATTERNS

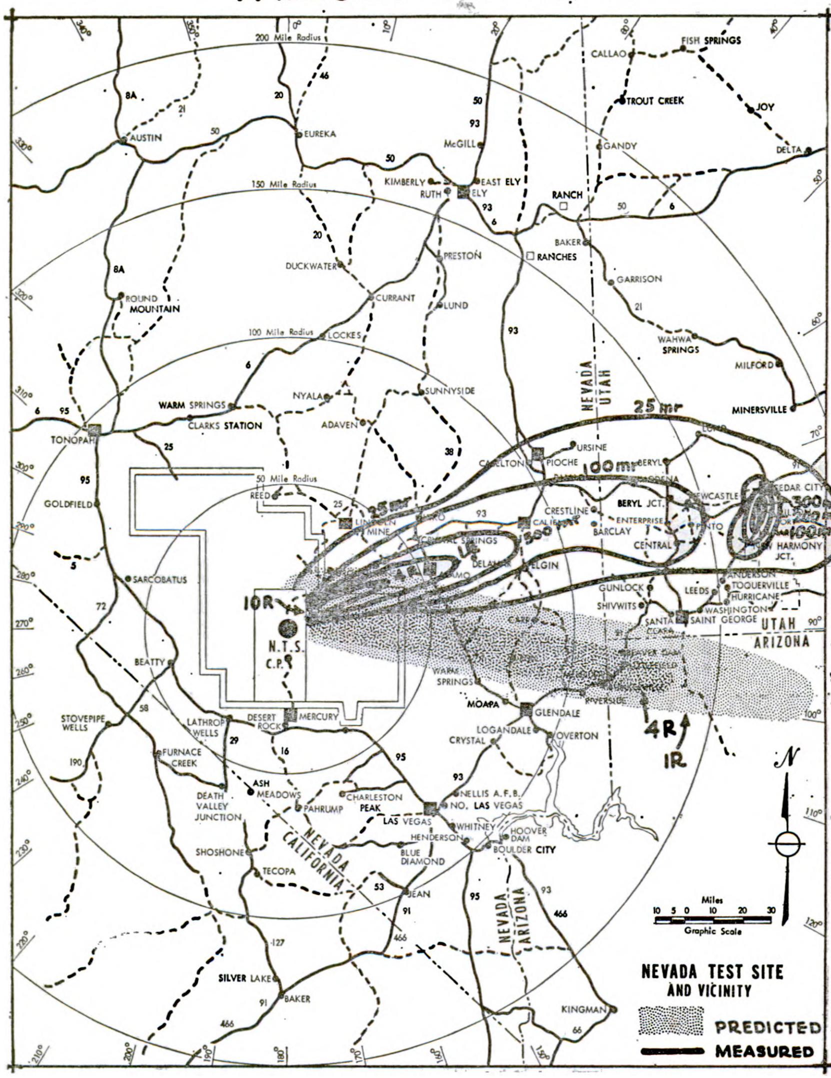

CHART 3

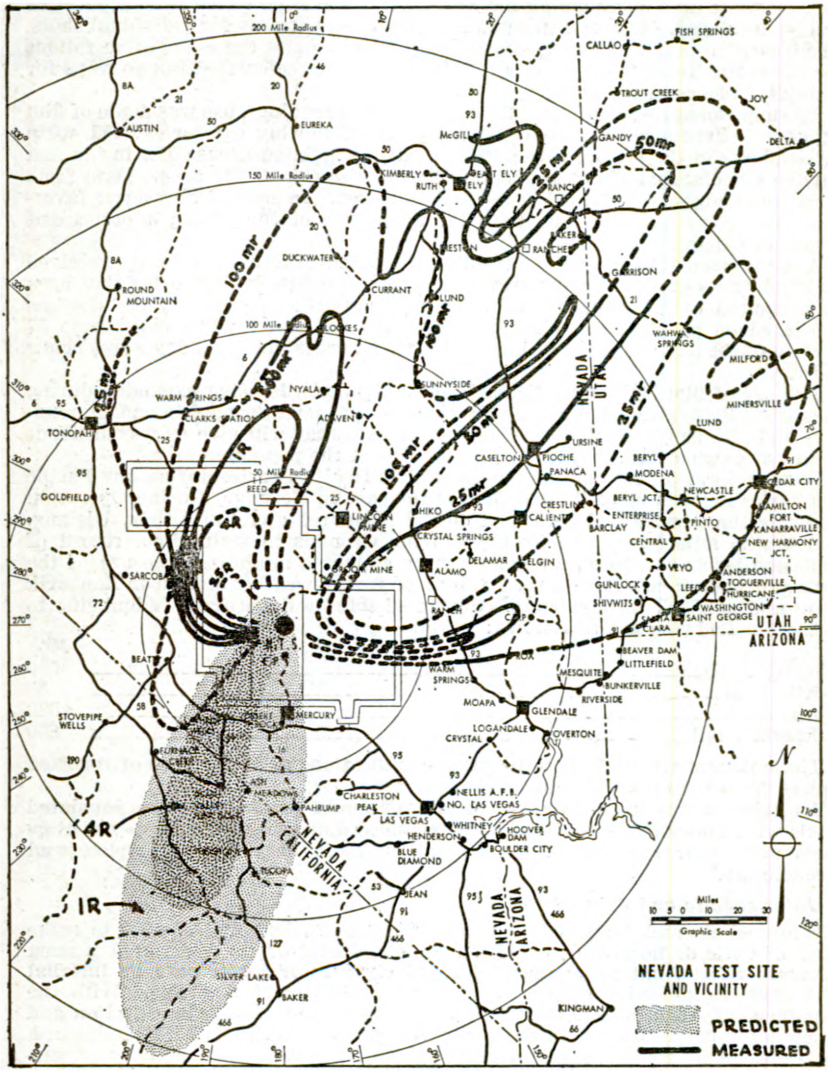
FALLOUT PATTERNS



Data from this report also indicates that cloud tracking with planes will generally give only an indication of the direction of fallout and cannot be relied upon for precise knowledge concerning deposition on the ground.[1] Most of the time it will give an idea of the direction from the point of detonation in which the fallout will occur, but this is not always the case. For public health emergency action it is not possible to depend entirely on cloud tracking as this will not always result in a reduction in exposure.

2. *Observed patterns of local fallout.*—A good deal of data has been obtained in the off-site area surrounding the Nevada test site from which fallout patterns can be developed. Charts I through III show such patterns for individual shots. The Teapot report contains a similar map which shows the cumulative fallout for the entire Teapot series and a tabulation of doses calculated in two ways for populated places in the area.[1]

To supplement these data calculated from meter readings, use was made of film badges.[1] Film-badge stations consisted of the following categories: 171 worn by residents in the off-site area; 106 posted in populated areas; 152 inside and outside schools; and 126 at nonpopulated points in the off-site area. Data from these film badges is contained in the Teapot report. In general they agree favorably with computed data and have the advantage of comprising a permanent record of exposures.

A comparison of the data from the film badges indicate that the dosage received by inhabitants in a particular area is less than the dose indicated for that area as measured by the same method. Approximately 94 percent of the dosages measured on people were within the 0 to 100 mr. range while only about 57 percent of the film badges posted in the populated areas indicated exposures below 100 mr.[1]

The use of film badges, particularly on individuals, is being expanded during Operation Plumbbob. We are also supplementing monitoring instrument readings and film badges with recording instruments that will give us a continuous record of gamma radiation levels in a number of the populated areas.

Data on local fallout obtained by the Public Health Service during any Pacific test series is much more limited than is the case in Nevada. During Operation Redwing the Service had personnel on the populated atolls of Utirik, Ujelang, and Wotho adjacent to the Pacific Proving Grounds to maintain a record of radiation levels and initiate any necessary action to minimize exposure of the natives to radiation.[2] Data was also obtained from a weather station on Rongarik Atoll and at JTF7 headquarters. Computed infinite doses from fallout due to Operation Redwing are as follows:

	Mr.
Ujelang Atoll	560
Utirik Atoll	50
Wotho Atoll	620
Rongarik Atoll	850

These figures are subject to the same qualifications as in the case of reported figures from Operation Teapot.

An attempt was made to supplement instrument readings on the populated atolls with film-badge data, but, due to technical difficulties which were not overcome until near the end of the operation, these data are incomplete and inconclusive.[3]

C. Intermediate and delayed fallout

Intermediate and delayed fallout are at concentrations and of ages to make them of little or no significance from the standpoint of acute external gamma exposure effects, but make them of relatively greater importance as internal beta emitters and with respect to the long-range biological effects. With the assistance of AEC, in 1956 and 1957, a routine system of sample collection and reporting in cooperation with State departments of health has been established. Our nationwide radiation surveillance network measures beta activity of particulates collected from air samples. Data from this network may be used to indicate the concentrations of radioactive materials which could expose humans to direct and indirect internal radiation hazards. Daily ambient gamma readings are also taken on a Geiger counter type of survey instrument.

---

[1] See footnote, p. 328.
[2] Unpublished report, Radiation Exposures Received on Populated Atoll as a Result of Operation Redwing.
[3] Unpublished report, Report on Experimental Film Badge Study During Operation Redwing.

Two references describe the collection and measurement of radioactivity deriving from the troposphere.[4 5] The Public Health Service, for a number of years, has been developing methods which assist the States in determining environmental radiation levels and interpreting those data in terms of Public Health significance.

Reference 4 summarizes the results of this operation and demonstrates the increasing amounts of fallout found in the United States from our, and foreign, nuclear tests. Reference 5 presents a more detailed study, principally in relation to rainfall, in the Cincinnati, Ohio, area.

Radioactivity in air, at any one location, is a daily variable and cannot quantitatively be predicted from a knowledge of test schedules. For public health evaluation there appears to be no substitute for routine measurement techniques. Deposition on the ground, to a large degree, is related to rainfall. Distribution of radioactivity, geographically, is then largely dependent upon local topography and meteorology. Rainfall may contain much more activity than do the surface waters which are fed by the rainfall. The protective factors offered by the watershed may give as high as 90 percent removal of gross radioactivity.

Fallout from many nuclear tests is now always present in the air we breathe and the water supplies for ourselves, our animals, and our plants. Since there are many variables it is necessary to make measurements and keep records on those factors in the environment which directly affect man in order to make a public health evaluation of the hazards.

VII. LOCAL FALLOUT: THE MECHANISMS BY WHICH IT CAN AFFECT MAN AND THE MEASURES HE CAN TAKE TO MINIMIZE EXPOSURE

B. Shelter and shielding and their effects

By the nature of the radiation involved, it has been observed that persons can protect themselves from the acute, external effects of the beta component of fallout simply by staying under cover at the time of fallout so that none or little falls on them. Virtually direct contact with the skin is necessary to produce beta burns. We have also observed that remaining in a building will provide some protection from gamma radiation as a result of the shielding effect of the structure and the distance from the fallout afforded by being in the building.

Some data on the gamma exposure protection afforded by this means was obtained during Operation Teapot by placing film badges inside and outside of school buildings.[1] A tabulation of the results is given in the Teapot report.

The significant feature of this data is the apparent protection offered by the school buildings. The upper exposure limit is reduced by a considerable factor on a gross basis and while about 95 percent of the inside exposures fall within the 0–100 mr range, only about 79 percent of the outside badges are below 100 mr.

During Operation Plumbbob the Service is going to attempt a much more complete documentation of the shielding effects of buildings. Film badges will be placed inside and outside of several different types of buildings and at several locations within the buildings. Film badge data will be supplemented insofar as possible with data from recording instruments which will give a continuous plot of time versus intensity of gamma radiation.

C. Other immediate emergency measures that can reduce hazard

The Public Health Service has operated under radsafe criteria in the Pacific and in Nevada which illustrate the type of emergency action which may be taken in the event of unexpectedly heavy fallout.[1 6] These were devolped jointly with JTF7 and the Nevada test organization respectively.

Both of these criteria recommend remaining indoors or under cover during periods of fallout to avoid direct contact with falling or settling radioactive particles. If exposed to fallout, personal decontamination is recommended including dusting and shaking off or laundering clothes and bathing with particular attention being given to washing under the arms, the groin, face, and hair. Covering of food and water to prevent ingestion of fallout particles is recommended.

[4] A Brief Review of the Public Health Service Radiation Surveillance Network, May 22, 1957.

[5] The Distribution of Radioactivity From Rain, by L. R. Setter and C. P. Straub, presented at the American Geophysical Union Meeting, April 29–May 1, 1957, Washington, D. C.

[6] Radsafe Emergency Instructions for Populated Islands.

An emergency measure recommended in the Pacific is to stand in the lagoon immersed as far as possible in the water while continuing to wash off exposed portions of the body. This recommendation is based on the fact that the fallout settles from the surface and allows water to attenuate the radiations. This fact has been checked in the field by PHS personnel.

In extreme emergencies, evacuation of contaminated areas may be indicated. This procedure is practical only if the evacuation will result in lower exposures than would result by staying within a shelter and if the location and intensity of the fallout pattern is known so that persons will, in the least possible time, be moved to areas of lesser contamination rather than into an area of higher contamination.

D. Dose and dose-rate versus time

During Redwing the PHS collected data at intervals ranging from once daily to once each hour with a gamma survey instrument at each of the atolls of concern.[3]

This data shows a phenomenon that has not, to our knowledge, been discussed to any great extent and that is the fact that, in the case of the larger weapons, the arrival of fallout may be extended over a period of several hours. Thus, although the fission products are decaying, this not apparent because of the continued arrival of new fallout. Typically, the radiation intensity will build up quite rapidly to a maximum, remain at or near this maximum for a period of several hours, and then start to decrease slowly. Thus a significant amount of exposure may be received before apparent decay starts.

VIII. DELAYED FALLOUT

A. The relative importance of internal emitters compared with external radiation in general for the long-run fallout situation

Elsewhere in our presentation mention has been made of the Public Health Service surveillance programs for air, water and milk. From the data which the Service has collected, and from other published information, we are following the obvious conclusion that, especially in relation to fallout, we must develop the trends of the amounts of internal emitters in man's environment and in his food chain. Because of the masking effect of natural background, external exposure effects relatable to fallout appear to be small in long-term potential when compared to the probabilities of accumulative buildup of internal emitters.

B. Deposition on and migration in soil and transport by surface waters

A number of Public Health Service studies are directly associated with the problems of migration and transport. Specific reference is made to the cooperative studies on high level radioactive waste performed by our staff from the Robert A. Taft Sanitary Enigineering Center at Oak Ridge National Laboratory.[7]

In relation to the problem of transport in surface waters, background and operational studies made by the PHS at the Columbia and Savannah River systems have a direct bearing, and provide research support data.[8] [9]

D. The effect of fallout on water supplies for human, agricultural, and industrial use

The Public Health Service has studied efficiency of normal water-treatment methods for the removal of radioisotopes from water supplies, and has made observations on the natural protective mechanisms.[10]

Depending, of course, on the exact nature of the radioactive compounds water-treatment methods offer limited protection. The degree of protection is on the order of 10 percent to 98 percent removal, or a decontamination factor ranging from 1.1 to 50.

The protective factors found in nature such as removal in watershed areas, are also within this range.[5] We have observed that in order to achieve removals of a much higher degree, as might prove necessary in the event of massive fallout during time of war or nuclear accident, the potential cost of effective water

treatment, such as ion exchange removal, increases tremendously. The requirements in treatment materials in quantity alone is probably prohibitive. At the present time we cannot state that modern water-treatment methods applicable to the general population offer substantial protection against fallout.

REPORT OF OFF-SITE RADIOLOGICAL SAFETY ACTIVITIES—OPERATION TEAPOT, NEVADA TEST SITE, SPRING, 1955

Prepared for the Test Division, Santa Fe Operations Office, United States Atomic Energy Commission; prepared by J. B. Sanders, Branch Manager, Las Vegas Branch Office, AEC; O. R. Placak, Off-Site Radiological Safety Officer, PHS; M. W. Carter, Deputy Off-Site Radiological Safety Officer, PHS

PURPOSE

The purpose of this report is to present a concise summary of off-site rad-safe activities during Operation Teapot and to serve as a source of information to interested AEC and health agency personnel. All pertinent data necessary to evaluate the exposure effects of the operation in populated areas are included. In the interests of brevity, selected data only are given for nonpopulated areas. Complete monitoring logs and detailed film badge results covering these areas are, however, available from the files of the Las Vegas Branch Office, AEC.

PLAN OF REPORT

This report is composed of the following general sections:
1. AEC radiological criteria for the protection of the public.
2. Off-site Rad-Safe Organization.
3. Methods and equipment used.
4. Public relations.
5. Résumé of individual shots are also included.

These individual sections cover the following materials: A summary of monitoring runs and dosages, airway closures, cloud tracking, and low-level terrain

surveys; a table which includes the dosages at all populated places where the external gamma dosage rate reading was greater than 0.1 mr/hr. and selected values in nonpopulated areas such as the maximum dosage and the dosage at points where the fallout crossed main highways; maps of fallout prediction, cloud tracking, low-level terrain survey, and ground-survey data.

6. Summaries.

In addition to the above, the following summaries and maps are included:

Integrated dosage for populated areas.
Film-badge data.
Milk-sampling data.
Water-sampling data.
Air-sampling data.
Maps: Integrated dosages from survey data.

1. AEC RADIOLOGICAL CRITERIA FOR THE PROTECTION OF THE PUBLIC

The Division of Biology and Medicine accepted the responsibility for establishing such criteria and procedures as were deemed necessary by the Atomic Energy Commission to protect the health and welfare of the general populace from the consequences of tests at the Nevada test site. The operational procedures adopted during Operation Teapot to meet these criteria were the responsibility of the Test Manager and were carried out by the Off-Site Rad-Safe Organization, under the direct supervision of the Support Director.

The basic criterion was that the whole-body gamma effective biological dose (EBD) for the off-site population should not exceed 3.9 roentgens over a period of 1 year. This total dose may result from a single exposure or a series of exposures.

The effective biological dose is an estimate of the biological damage dose taking into account the length of time for delivery of a given dose and the reduction of dose due to (*a*) shielding afforded by buildings, and (*b*) the process of weathering.

The EBD, as computed from integrations of dose rate readings, is the sum of three-fourths of the maximum theoretical radiation dose from time of fallout to 15 days later and one-half of the maximum theoretical dose from the 15th day to 1 year.

Values of gamma dose rate readings that will satisfy this criterion for particular situations are given in graphs I, II, and III.

Personnel should be requested to remain indoors with windows and doors closed when the gamma dose rate reading, measured by a survey meter held 3 feet above ground, reaches the values given in graph I at the times indicated.

Personnel decontamination should be practiced when the gamma dose rate readings, measured by a survey meter held 4 inches from the contaminated area, equals or exceeds the values given in graph II.

Vehicles should be cleaned inside and out when the gamma dose rate readings, measured by a survey meter held 4 inches from the surface, equals or exceeds the values given in graph III.

It is recommended that when the predicted fallout across a main highway will be equivalent to a 10 roentgen infinity gamma dose or higher, that vehicles will be held until after fallout has essentially ceased.

The above criteria do not apply to domestic or wild animals since levels of radiation which would be significant to them would have to be higher than those specified.

A more complete discussion of criteria is contained in a Division of Biology and Medicine, AEC, publication entitled "Atomic Energy Commission Radiological Safety Criteria and Procedures for Protecting the Public During Weapons Testing at the Nevada Test Site" dated February 1955.

2. OFF-SITE RAD SAFE ORGANIZATION

Off-site rad safe operations were a responsibility of the Test Manager and the Support Director, and were directed by the Deputy Director for Support, who was the Off-Site Operations Chief, and the PHS officer in charge, who was the Deputy Off-Site Operations Chief.

The various functions of the Off-Site program as outlined in the scope of work immediately following were carried out by personnel from the AEC, PHS, DOD, Reynolds Electrical and Engineering Co., and Silas-Mason Co.

Scope of program

The off-site rad safe program dated January 10, 1955, was designed to accomplish the following objectives:

1. To accurately delineate the duration and extent of the fallout pattern as determined by ground surveys.
2. To verify the above by low-level terrain surveys using aerial monitoring.
3. To determine, by aerial tracking, the intensity and direction of the radioactive cloud.
4. To determine the actual exposures to people and livestock, by the above methods, by film-badge exposure records and by air, milk, and water samples.
5. To obtain data, at points close to the Nevada Test Site, to improve the formulae used in fallout prediction.
6. To conduct a continuing public relations and education program.
7. To record, map, and report the data obtained.

Responsibilities of various agencies

Atomic Energy Commission: The AEC was responsible for the overall administration of the program and of the work of other agencies outlined in more detail below. This includes policy decisions, budget requirements, procurement of materials and supplies, and all other support requirements.

Public Health Service: All ground monitoring crews were composed of regular and reserve PHS personnel with the exceptions noted under Silas Mason Co. and Los Alamos Scientific Laboratory employees W. S. Johnson and C. P. Skillern, who assisted in prior planning and during the first five shots.

This group was directly responsible for accomplishing the objectives set forth in items 1, 4, 5, 6, and 7.

Department of Defense: This agency supplied and maintained the survey instruments used and also supplied and processed all film badges.

Additionally, air support was furnished for low-level terrain survey and cloud-tracking purposes.

Reynolds Electrical & Engineering Co.: This organization furnished support facilities including procurement of supplies and services, stenographic and communications personnel, maintenance of laboratory and automotive equipment, and other necessary items.

Silas Mason Co.: Personnel were furnished for plotting and mapping of the data obtained. Four Silas Mason employees were used in monitoring operations at Lincoln mine and other areas near the Nevada test site.

Organization and operation of ground and air support units

All of the data for determining the effects of the operation in off-site areas were obtained by these units. Consequently, the method of organization and operation of these units is given, in some detail. The following discussion excludes one important feature, public relations, since this is the subject of a subsequent section.

Offsite ground units: These teams were composed of regular and reserve USPHS personnel. Originally, there were 33 positions filled, although in the late stages of the operation the number of men available was reduced to 20. Including replacements, a total of 66 men were used.

The offsite rad safe plan established areas of local responsibility. Twelve of these zones were organized, each with a zone commander and the additional personnel required for successful operation. Within an assigned area the zone commander was responsible for public relations, dissemination of information, reporting grievances, collection of samples, placement and collection of film badges, and normal monitoring in the absence of specific instructions from headquarters.

The location of the various zone headquarters with personnel (at full complement) and vehicular requirements are shown in the following tabulation. The laboratory personnel and unassigned monitors at Mercury who could be dispatched to areas of greatest concern are indicated.

Zone headquarters	Personnel	Vehicles	
		Radio	Nonradio
1. Tonopah, Nev.	2	1	------
2. Mercury, Nev.	1	1	------
3. Las Vegas, Nev.	1	1	------
4. Glendale, Nev.	2	1	------
Mesquite, Nev.	1	1	------
5. St. George, Utah	2	1	------
6. Cedar City, Utah	2	1	------
7. Beaver, Utah	2	1	------
8. Alamo, Nev.	2	1	------
9. Caliente, Nev.	2	1	------
10. Pioche, Nev.	2	1	------
11. Ely, Nev.	3	1	1
Eureka, Nev.	1	1	------
12. Lincoln mine (Tempiute), Nev.	2	1	1
Headquarters	4	1	------
Unassigned monitors at headquarters	4	4	------

A complete roster of all off-site personnel is contained in appendix I.

Off-site communications were maintained by telephone and radio, telephones being used only when the radio network was not operating. This dual system of communications operated well and satisfactory contact with field personnel was maintained.

The radio net was composed of a net control station at Mercury, fixed and semifixed relay stations and mobile receiving and transmitting sets in the monitoring vehicles. The semifixed stations were mounted in trailers and could be relocated as required by a particular operation. The normal period of operation was from 0800 to 1600 each day. Operation subsequent to a shot was continuous until the all-clear announcement by net control.

The type, normal location, and personnel of the radio net at the start of the operation are given in the following tabulation.

Type station	Base station	Number of personnel
Control station	Mercury, Nev	2
Fixed	Currant, Nev	2
Do	St. George, Utah	2
Do	Lincoln Mine, Nev	2
Semifixed	Sunnyside or Warm Springs, Nev	1
Do	Glendale, Nev	2
Do	Alamo, Nev	2
Do	Caliente, Nev	2
Do	Pioche, Nev	2
Do	Ely, Nev	2
Do	Eureka or Geyser, Nev	2

A normal abbreviated sequence of events for ground monitoring operations follows:

Preshot:
1. Decision to proceed tentatively at evening weather briefing.
2. Field stations alerted—background samples started.
3. Radio stations and unassigned monitors dispatched as required.
4. Decision to proceed confirmed at early morning briefing.
5. Additional monitors dispatched as required.
6. Special preparations made, such as for roadblocks and evacuation.
7. Monitors advise people in their area.

Postshot:
8. All roads and populated areas in fallout area monitored as directed by headquarters.
9. All other monitors operate in manner prescribed in general instructions.
10. Monitoring of roads discontinued when no further information can be obtained.

D+1 following day:
11. Remonitoring performed as required.
12. Air samples, milk and water samples were collected as required.
13. Samples and data dispatched to laboratory for processing and counting.
14. Film badges collected as directed by headquarters.
15. Complaints and grievances investigated.
16. Field men contlnle public relations program.
17. Headquarters prepares report of the operation.

Off-site air support unit: This unit was staffed by Air Force personnel and including replacements was composed of approximately 20 airmen. The mission of the unit was:

1. To make low-level terrain surveys along the path of the fallout following a shot, and preshot reconnaissance surveys to check isolated areas for persons or animals.
2. To track the radioactive cloud or clouds at various altitudes and to record and plot the data obtained.
3. To assist the CAA in directing closure of airways in which a radiation hazard might develop based on preshot predictions and to recommend necessary changes based on actual cloud-tracking operation following a shot.

The aircraft assigned to the unit and their functional use are tabulated below. The detection devices used were T-1B and MX-5 type instruments. The air-to-ground conversion curve is shown as graph IV.

Type of aircraft	Number available	Use
C-47	2	Low level terrain surveys at 200 to 600 eet.
B-25	1	Cloud tracking. 10,000 to 15,000 feet.
B-29	1	Cloud tracking, 20,000 to 25,000 feet.
B-50	1	Cloud tracking, 27,000 to 32,000 feet.

A brief résumé of the technique of low level terrain survey and cloud tracking operations follows:

Low level terrain survey

Prior to the initial shot a terrain survey was conducted on D–1 for the purpose of locating persons and/or animals in the vicinity of the test site. On subsequent shots, the D–1 survey was conducted only upon request of the offsite operations chief or when reports indicated new concentrations or considerable changes in known livestock locations. Information was kept current by noting such positions whenever a low level survey of any type was flown.

On shot day, after sufficient time had been allowed for the fallout to occur, a low level mission was flown to delineate the fallout zones. To accomplish this mission, the aircraft was initially maneuvered to a point near ground zero to cross the suspected fallout zone at an angle of about 90°. From this starting point the fallout path was repeatedly crossed at altitude varying from 200 to 600 feet above the terrain, the interval between successive crossings varying from 3 to 10 miles, depending on the local terrain features. If possible, an altitude of about 300 to 500 feet above the terrain was maintained, since these proved to be the best operating levels for accurate readings on the radio altimeter. Since the conversion of the air reading of the radiac meter to a corresponding surface reading is dependent upon the altitude of the aircraft above the terrain, it was necessary that this factor be known as accurately as possible. In converting these readings, correlation curve (graph IV) was used. This curve was plotted from data obtained by flying a C–47 at various known altitudes above areas with known radiation intensities. The correlation between readings obtained by air surveys and those obtained by ground monitors was in reasonable agreement throughout the operation. The aerial survey proved invaluable in obtaining data in regions inaccessible to ground parties, thereby making it possible to more completely determine the actual fallout patterns.

Cloud tracking

In order that the tracking aircraft could avoid deep penetrations of the cloud, the cloud was approached from one side at an angle of approximately 30° until a reading of 10 mr/hr or higher was obtained on the radiac meter. At this point the aircraft was turned out of the cloud as sharply as possible, and the cloud approached again at a different point, in this case the suspected leading edge. This procedure was repeated throughout the mission, with the result that the successive positions of leading edge and the two sides of the cloud were determined and provided a definite cloud track when plotted on a map. The cloud was tracked either until it had dispersed to such an extent that it no longer followed any particular direction or until the tracking aircraft had to return to base for operational reasons.

3. EQUIPMENT AND METHODS

Equipment was selected, located, and operated in such a manner as to insure maximum effectiveness in the collection of physical data pertaining to:

1. Surface levels of activity (normally, 3 feet above ground level), as determined by the use of survey meters.
2. Concentration of airborne activity.
3. External gamma dose received by persons and places by the use of film badges.
4. Activity contained in milk and water.

Each of these procedures is described in the following paragraphs, as the methods for sampling fallout have not been standardized. Detailed operating procedures along with data forms were prepared and distributed to all personnel during their briefing and orientation period. These written instructions contained general background information which augmented their usefulness as routine operational guides.

1. Surface radiation levels.—Portable monitoring (survey type) instruments were used to measure radiation intensity. These rates, along with other pertinent data, were then used to calculate the gamma dosage received at a particular point. Each monitoring vehicle was supplied with 4 survey instruments, 2 MX–5's and 2 T1–b's (range 0 to 20 mr/hr and 0 to 50 r/hr respectively). Measurements of gamma only were made at hip height above terrain.

Instruments were checked and calibrated before issue. Periodic calibrations were made on each instrument in the field with the minimum calibration period being before and after each detonation. Cobalt 60 sources were used for calibration both at headquarters and in the field.

During monitoring runs, the instruments in use were left "on" and monitoring was performed from inside the vehicle as long as background only was encountered. General readings were recorded at a maximum of 10-mile intervals. When the level encountered was twice background, monitoring was done outside and at least 25 feet from the vehicle. More frequent readings were then taken dependent upon the levels encountered. Distances were quite important as measurements were found to vary significantly between points which were less than one-tenth of a mile apart.

In general, it was possible to have at least one monitoring team in an area during fallout. Such being the case, the time of fallout at this particular point could then serve as a basis for estimating fallout times in other areas. This data is necessary to accurately calculate a radiation dose using intensity values obtained from survey meters.

Intensive monitoring was conducted during the early stages of fallout to determine as soon as possible the pattern and the intensities in populated areas and at strategic places such as major highways. Remonitoring was performed to be sure fallout was complete, and to obtain measurements using different instruments operated by different individuals. Monitoring was continued until it was thought no further useful data could be collected or because another detonation was imminently scheduled. It was necessary in a few instances to compromise slightly between completing today's shot activities and preparation for tomorrow's shot.

2. Airborne concentrations.—Staplex high volume air samplers were used with an MSA comfo-all dust filter for the collection of airborne contaminants. The rate of flow was in the range 1.1 to 1.3 cubic meters per minute. The standard sampling period was 28 hours beginning at shot time. Background samples, however, were run prior to each shot. The 28-hour sampling period included 7

filter changes ranging from time periods of 1 to 16 hours. More frequent changes were made when fallout occurred or when the flow rate decreased appreciably.

All filter samples were returned to the laboratory for gross beta counting. Proportional counters in conjunction with Sr-90+Y-90 standards were used for laboratory counting. For purposes of calculation, activity measured was extrapolated to midcollection time. The method of calculation resulted in a visual presentation of fallout pattern and distribution. Air activity concentrations were finally expressed as total microcuries per cubic meter of air averaged over the sampling period.

Approximately 230 individual filter samples were collected and counted following each detonation.

3. Film badges.—DuPont film packet type 559 film badges, consisting of two film components (type 502 and type 606), were used. The badges were placed in communities, along highways at 10- to 15-mile intervals, in strategic desert locations, on representative people in various towns and ranches, and in all known schools in the off-site area with the exception of the Las Vegas school system. At schools, badges were placed inside the building, outside, and usually on at least one member of the faculty.

Personnel badges were clipped on, while the "area" badges were mounted with either masking tape or placed in glassine envelopes which were tacked to a post, tree, or building. Of course, the badges themselves were sheathed in a watertight plastic envelope.

Badges were changed at frequent intervals. The collected badges were returned to the laboratory and the dosage calculated by comparing their net optical density to that if similar film packets exposed to a CO-60 standard.

Approximately 600 film badges (per change) were in place at the various stations before, during, and following the test series. Using this procedure, data are available on background; incremental additions of activity; overall exposure during the time period covered; the effect of certain structures on reducing gamma radiation; and, by comparison with dosages calculated from monitoring readings, the effectiveness of survey meters for obtaining information from which dosages are calculated.

4. Activity contained in milk and water.—Milk samples were collected from selected herds in each zone, from retail stores, from all processing plants in the off-site area, and any herd which was thought to be affected by fallout. Such a program should reveal the maximum activity contained in milk as well as the average levels to which the general population would be exposed. Samples were collected periodically with enough flexibility in sampling to insure adequate samples to define any given situation.

Water samples were collected from surface and subsurface water supplies, irrigation canals, and stock-watering ponds. Specific sampling stations were established and sampled routinely. Here again, samples were taken from any watering point which could possibly be affected by fallout.

The first sets of water and milk samples were collected prior to the start of the series. After assay, these data were used as the normal background radiation level. It could then be determined if the series produced contamination and the magnitude of such contamination.

Milk and water samples were sent to the laboratory for assay. Yet ashing, using nitric acid and hydrogen peroxide, was the method of sample preparation. Residues were transferred to counting dishes; a wetting agent added; dried under infrared lamps; and counted in proportional counters. Sr-90+Y-90 standards were used. The results are presented as microcuries per milliliter at the time of collection and/or the time of fallout.

5. Personnel monitoring.—Every person actively engaged in the off-site program was supplied with Du Pont type 559 film packet and a 1 roentgen Cambridge dosimeter. The dosage recorded by the film badge was used as the official record exposure, as required by the test manager. The dosimeter was to be used for information of use to the individual and not as a part of the official record.

6. Laboratory equipment.—Laboratory equipment consisted of four proportional counters which were fed methane gas. Three were connected to count rate meters and Esterline-Angus recorders while the fourth was connected to a decade scaler. The probes and sample housings were specifically designed to accommodate the type samples collected.

Two of the probes were used with a scanning device which enabled the counting of up to 100 micocuries on a single sample. These arrangements were used on the more active air samples.

All laboratory counting equipment was designed and built by the instruments division of the Los Alamos Scientific Laboratory in Los Alamos, N. Mex.

4. PUBLIC RELATIONS

It was recognized that adequate public relations is necessary to the successful operation of the Nevada test site. The off-site program was designed to facilitate good public relations. This was accomplished by contacts and talks prior to the series, by the system of zone commanders who were largely responsible for good relations within a specified area, by following up each incident reported immediately and, of course, by the general program carried out by the Joint Office of Test Information.

The public relations program during the operation laid the general ground work for a continuing public relations program to be carried out in the interim periods.

In general, relations with the off-site populace were good. People were particularly appreciative of the fact that monitors were permanently stationed in their communities. Opinions expressed to monitors indicated that local populations felt more secure with this arrangement with regard to radiation hazards and that they appreciated having a local contact to go to for information or with complaints. Off-site personnel were able to carry out a continuous educational program since full advantage of their presence in the community was taken and they were asked to be on the programs of civic clubs and other organizations, to furnish material for radio programs and newspapers and to aid in school programs.

Prior arrangements.—Prior to the start of the series, all of the large population centers in the area were visited by off-site personnel to inform people of the forthcoming tests and the manner in which off-site problems would be handled.

Immediately before the start of the series most of these communities were revisited by a group consisting of the Test Manager, Scientific Advisor, Test Director, Support Director, Information Director, Off-Site Operations Chief, and the senior PHS officer. A series of talks were given in Caliente, Pioche, Ely, and Tonopah, Nev., and St. George and Salt Lake City, Utah. In these talks the value of continental nucler tests to the country was stressed and the precautionary measures to be taken with regard to public safety were outlined. People were informed of the plans to station monitors in their community and that these men were expected to become a part of the community during their stay and to be of service to it in regard to public safety, information or in any other way.

From 7 to 10 days before the initial detonation, the monitors with their equipment moved into the community, familiarized themselves with the area, made acquaintances and actively took over the job of public relations.

Liaison activities.—Arrangements were made to keep those health officials who might be primarily concerned, informed of the activities at the test site. The States normally involved were Nevada, Utah, California, and Arizona, and the State health officers of these States were advised routinely by phone of any fallout situation that might affect areas under their jurisdiction. The personnel advised in these instances were:

Nevada: Dr. Daniel J. Hurley, State health officer.
Utah: Dr. George A. Spendlove, State health officer.
California: Dr. John M. Heslep, designate of State health officer.
Arizona: Dr. C. G. Salsbury, State health officer.

In addition to these arrangements, contacts were made with affected USPHS officials and with local health officials.

Activities of zone personnel.—Zone personnel conducted a public-relations program on an informal and down-to-earth basis. They formed a wide acquaintance in their respective areas, participated in local events and took their instructions to become a part of the community seriously; as for example, the monitor at Glendale who became a Sunday school teacher, or the one in Alamo who plastered a ceiling in one of the hotel rooms. Such intimate association with the people in the area was good practical public relations, and while it may not have altered completely basic public opinion regarding the tests, it at least made the explanations of zone personnel more acceptable.

Every opportunity to reach the public through talks and film showings was accepted. Practically every person throughout the off-site area saw at least one film and listened to at least one discussion by monitors. This was accomplished through civic clubs, schools and PTA, and other groups. In this connection, it should be stated that the new film Atomic Tests in Nevada received enthusiastic reception. From the remarks made to zone personnel, it appears that general feeling was that, for the first time, the public was being shown exactly what happened during a shot.

A complete listing of public relations contacts is not available, but the partial list of film showings tabulated in table 1 will indicated the scope of this activity:

Total people seeing films.				[1] 7,550

[1] Not a full count. Conservative estimate made when attendance figure was missing.

In addition to these semiformal contacts, a large number of individual contacts were made. One interesting example of this indicates the public relations value of the film badge program. During a routine change of a personnel film badge in Goldfield, Nev., the wearer remarked that "there must be some fine people at the test site, since they were taking such precautions even in a small place like Goldfield." It must be recognized, however, that although relations throughout the off-site area were generally good, there are some specific areas of difficulty. An example of this is the attitude of the newspaper editor in Tonapah, who, contrary to editorial opinion in general, has maintained a highly critical attitude toward test activities.

Other informational material was distributed. The news releases of the Joint Office of Test Information were widely used by monitors. However, the most valuable piece of educational material was the little yellow booklet, Atomic Test Effects in the Nevada Test Site Region. Thousands of these were distributed through schools, post offices, motels, and by other means throughout southern Nevada and Utah, and in parts of Arizona and California. This was very well received. In fact, some people thought so highly of it that they requested copies to distribute on their own. Many of these booklets were picked up by tourists and were probably carried to all parts of the Nation.

Special investigations.—It was inevitable that numerous incidents requiring investigation should arise. These were of three types, as they effected material things, people, or livestock. All that came to the attention of the off-site program were investigated and are documented in the files.

With respect to material things, the greatest number of complaints were from prospectors. An explanation of the transient nature of radioactivity from fallout was generally acceptable. In all cases where blast damage was reported, forms for damage claims were mailed and these are being processed in the customary manner. In those cases where contamination from radiation were reported, such as on vehicles, the zone personnel investigated and were generally able to satisfy people during these visits that no hazard existed.

A number of cases of radiation damage to people were reported. These were investigated by the Cedar City Zone commander, Dr. Clinton G. Powell, who is a

PHS doctor. This procedure was so useful that it became apparent that it was a mistake to require medical personnel to also act as zone commanders. In any future operation, a qualified doctor with radiation experience should be available within the off-site program for the sole purpose of investigating claims of personal radiation injury.

Prior contacts were made with the local doctors. All investigations were made by working with local doctors. This procedure eliminated any chance of criticism about professional ethics, increased the patient's confidence in the procedure and did much to educate the local physicians in regard to radiation matters.

The general procedure was to have the patient brought to the local doctor's office. If necessary, off-site monitors provided the transportation. There both doctors examined the patient and arrived at a decision. Any costs were billed through Reynolds Electrical & Engineering, Inc.

In no case, of those examined, were there symptoms that could be definitely attributed to radiation injury. Many cases turned out to be some common ailment, diaper rash, in one case. However, the reports of eye irritation were so persistent that this matter should be investigated in order to prove or refute the widespread belief that this is due to test activities.

Reports of injury to livestock were reported by zone personnel and investigated during the series by veterinarians (Maj. Grant Kuhn and Col. Bernard Trum) from the AEC-University of Tennessee Agricultural Farm at Oak Ridge or by Dr. Wendell Brooksby, of the Utah State Agricultural College. There is little doubt that reputed livestock damage will continue to be reported for some time after the tests since livestock culture is such an important part of the economic life of the area. This suggests the desirability of the continuous services of a veterinarian with radiological training and of a sound investigative program.

5. RÉSUMÉ OF INDIVIDUAL SHOTS

This section includes a brief summary of results for each nuclear device detonated during the test series. While only condensed highlights are presented here, complete data are contained in the files of the Las Vegas branch office.

Each shot summary has been arranged, for ease of comparison, according to the outline below:

1. General information
2. Airway closure pattern
3. Cloud tracking
4. Low-level terrain survey
5. Ground monitoring results
6. Selected gamma dosages
7. Number of ground readings taken (above 0.1 mr./hr.)
8. Comparison of maps
9. Airborne radioactivity concentrations
10. Table—External gamma dose in populated areas and at selected nonpopulated points
11. Maps
    - (a) Prediction
    - (b) Cloud track
    - (c) Low-level terrain survey
    - (d) Ground monitoring
    - (e) Combined air and ground results

In some cases, all of the above maps are not available. For exemple, for certain shots it was not possible to obtain aerial results due to the extremely light fallout. On 1 occasion there were 2 detonations on the same day. In this case the results from the two individual detonations have been combined.

The maps are given in terms of infinite dose and/or effective biological dose.

Comparison of maps is done on an extremely gross basis. The major points of comparison are direction of fallout and relative magnitude of fallout, as determined from length of specific isodose contours.

Following the summary for Zucchini (the last shot of the series) is map 1 which represents the cumulative fallout plot for Operation Teapot. The map is plotted in terms of infinite dose and reflects both aerial and ground monitoring results.

For orientation purposes, as to the shot names, the times and dates of detonation, the type of detonation, and the firing area, the following tabulation is presented.

Devices detonated during Operation Teapot

Name	Detonated		Type	Area
	Time	Date		
Wasp	1200	Feb. 18	Airdrop	7—Yucca.
Moth	0545	Feb. 22	300-foot tower	3—Yucca.
Tesla	0530	Mar. 1	do	9—Yucca.
Turk	0520	Mar. 7	500-foot tower	2—Yucca.
Hornet	0520	Mar. 12	300-foot tower	3—Yucca.
Bee	0505	Mar. 22	500-foot tower	7—Yucca.
ESS	1230	Mar. 23	Subsurface	10—Yucca.
Apple	0455	Mar. 29	500-foot tower	4—Yucca.
Wasp Prime	1000	Mar. 29	Airdrop	7—Yucca.
HA	1000	Apr. 6	High altitude	Yucca.
Post	0430	Apr. 9	300-foot tower	9—Yucca.
MET	1115	Apr. 15	400-foot tower	Frenchman.
Apple II	0510	May 5	500-foot tower	1—Yucca.
Zucchini	0500	May 15	do	7—Yucca.

Wasp

Wasp was an airdrop which was detonated at approximately 800 feet on February 18, 1955, at 12 noon. The shot took place in test area 7 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 7:15 to 10 a. m.
2. A sector, bounded by radii at 100° and 210°, extending 175 and 120 nautical miles, respectively, from the end of the 210° radius extend due east to JF3015, then due north to intersection with 100° radius, was ordered closed from the surface to 30,000 feet from 8:45 to 11 a. m.
3. The following area was ordered closed from 10,000 feet to 30,000 feet from 11 a. m. to 5:30 p. m. From FF3030 due south to FE3000, then due east to ME0000, then follow Arizona-New Mexico border to 4 corners, then west to HH3000, then return to initial point.

Due to mechanical difficulty with the drop aircraft, the time of the shot was moved ahead, causing a corresponding shift of 4 hours in all closure times.

The cloud was tracked, as indicated on the accompanying map, from H plus 80 minutes to H plus 2 hours. In addition to reports from the B–25 tracker, reports from sampler aircraft were used to chart the cloud movement. Maximum cloud height observed was 20,000 feet. The cloud was tracked to a point southwest of Las Vegas (Goodsprings, Nev.), at which point it was so scattered as to become relatively undefined.

On D–1 day a low-level survey was made by one C–47 to locate and record the position of persons and/or animals in remote areas within the predicted fallout zone. On D–day the survey aircraft took off at approximately H plus 3 hours 45 minutes and reported no significant off-site contamination.

Ground-monitoring runs, which indicated activity substantially above background, were made along U. S. 95 between 10 miles east of Mercury Road and Indian Springs Air Force Base; on Nevada 52 between 12 miles south of U. S. 95 and the southern end of the highway; and along Nevada 85 from 22 to 32 miles southeast of Pahrump, Nev.

The maximum effective biological dose for populated area was 0.7 mr. at Cactus Springs, Nev. The maximum effective biological dose at a nonpopulated point was 55 mr. on Nevada 85, 28 miles southeast of Pahrump, Nev.

Only 10 individual monitoring readings above 0.1 mr./hr. were recorded.

Fallout was very light as indicated by ground monitoring and also by the lack of data from the low-level terrain survey.

No air samples were collected which indicated an air activity concentration in excess of $10^{-4} \mu c/m^3$.

Wasp: External gamma dose in populated areas and at selected nonpopulated points

Moth

Moth was a 300-foot tower detonation which was fired at 5:45 a. m. on February 22, 1955. The shot took place in test area 3 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 5:15 to 8 a. m.

2. A sector bounded by radii at 120° and 180°, length of radius 125 nautical miles, was ordered closed from 15,000 to 26,000 feet between the hours of 6:45 and 8:15 a. m.

3. Finally, a large rectangular area, primarily in Arizona, was closed at the same altitudes as the above sector from 8 to 11:45 a. m. The boundaries of this area, as defined by Georef coordinates, were:

Continue the 120° radius to KE0030, then due south to Tucson, Ariz.

Continue the 180° radius to EE0050, then southeast to HC0000.

As the reports of the tracking aircraft came in, the following changes were made in the closure pattern:

At 6:30 a. m., the radius bounding the sector defined in (2) above was shifted from 120° to 90° out to KH0000, then due south to Tucson, Ariz.

At 6:45 a. m., the area south of the north edge of Airway Green 4 was opened at all altitudes.

At 6:48 a. m., all areas were opened to traffic at 24,000 feet and above.

The cloud was tracked, as indicated on the accompanying map, from H plus 18 minutes to H plus 3 hours 25 minutes. Reports from B–25 tracker and sampler aircraft were used. The maximum cloud height observed was 24,880 feet. The maximum height of the cloud decreased as it progressed on a general bearing of approximately 130°, stabilzing at roughly 22,000 feet. The path followed by the cloud took it north and east of Las Vegas, Nev., and extended for approximately 110 nautical miles when the tracking aircraft were recalled.

As an indication of the magnitude of radiation to be expected should a commercial aircraft penetrate the cloud, two F–84 aircraft were flown into the cloud and were checked for contamination upon return. The pertinent data are presented in the following tabulation:

	Aircraft No. 1	Aircraft No. 2
Time of penetration	H+3 hours	H+3 hours.
Duration in cloud	30 seconds	13 minutes.
Altitude	22,500 feet	20,000 feet.[1]
Maximum intensity	800 mr./hr	500 mr./hr.
Average intensity	300 mr./hr	400 mr./hr.
Time of landing	H+5 hours	H+5 hours.
Readings on various aircraft components:		
Drive brakes	100 mr./hr	480 mr./hr.
Wing tips	48 mr./hr	140 mr./hr.
Nose	50 mr./hr	180 mr./hr.
Impeller section of engine	100 mr./hr	480 mr./hr.
Pilot dose	30 mr	150 mr.

[1] Descending along cloud to 10,000 feet.

The low-level terrain survey was conducted by 1 C–47-type aircraft which took off at H plus 7 hours 45 minutes, completing the mission at H plus 10 hours. The contamination pattern disclosed by this survey is plotted on the accompanying map.

Monitoring runs, which indicated activity substantially above background, were made on the desert road running north from Indian Springs, Nev., along the desert road from Groom Road to Frenchman Flat; on the game preserve road running north from U. S. 95; on U. S. 93–91 in the vicinity of Dry Lake, Nev.; and along Nevada 40.

The maximum effective biological dose for a populated area was 130 mr. at Dry Lake, Nev. The maximum effective biological dose at a nonpopulated point was 5,900 mr. 22.8 miles north of Indian Springs, Nev., on a desert road.

Approximately 60 individual monitoring readings above 0.1 mr./hr. were recorded.

The H minus 4-hour prediction map indicated fairly good agreement with the factual maps. With very little shear in the fallout pattern, expected times of fallout could be readily predicted. The small amount of fallout to the northeast

was not detected by the low-level terrain survey. The ground survey as well as the aerial survey showed that the 1 r. infinite contour crossed U. S. 93–91 at a nonpopulated place.

The maximum air radioactivity concentration measured was $4.4 \times 10^{-3} \mu c/m^3$. at Cedar City, Utah. This represents the average air concentration for a 28-hour period starting at shot time.

Tesla

Tesla was a 300-foot tower detonation which was fired at 5:30 a. m., on March 1, 1955. The shot took place in test area 9 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 5 a. m. to 8 a. m.
2. A sector bounded by radii at 65° and 125°, length of radius 60 nautical miles, was ordered closed at all altitudes from 5 a. m. to 10 a. m.
3. An extension of this sector to a radius of 90 nautical miles was ordered closed from 13,000 to 19,000 feet from 7:30 a. m. to 10 a. m.
4. A further extension of this sector to a radius of 160 nautical miles was ordered closed from 20,000 to 28,000 feet from 6:30 a. m. to 10 a. m.
5. At 7:47 a. m. the altitudes in sector (3) above were changed to close only between 16,000 to 19,000 feet and the circle in (1) above was opened at all altitudes except for the sector area (65°–125°).

The cloud was tracked as indicated on the accompanying map from H plus 35 minutes to H plus 2 hours and 55 minutes. In addition to reports from the B–25 tracker, reports from sampler aircraft were used to chart the cloud track. Maximum cloud height observed was 30,000 feet, which stabilized rather quickly to 27,000 feet. The cloud was tracked to a point near the northernmost part of Lake Mead, at which time aircraft were recalled.

The low level terrain survey was performed by one C–47 aircraft, which took off at H plus 7 hours and completed the mission at H plus 11 hours and 45 minutes.

The monitoring runs, which indicated activity substantially above background, were made on the Game Preserve Road north of U. S. 95; on U. S. 91 between Beaver Dam, Ariz., and Washington, Utah; along Utah 64 south of St. George, Utah; on Utah 15; on Utah 17; on Utah 18; along the Mormon Mesa Road north of U. S. 91; and on U. S. 93 approximately 27 miles south of Alamo, Nev.

The maximum effective biological dose for a populated area was 177 mr. at Santa Clara, Utah. The maximum effective biological dose at nonpopulated point was 34,000 mr. 10.5 miles south of Groom Road on Papoose Lake.

Approximately 190 individual monitoring readings above 0.1 mr/hr were recorded.

A comparison of the prediction map and the factual maps indiactes good agreement in both direction and magnitude of fallout. Ground monitoring did not indicate fallout in Carp, Nev., as shown on the terrain survey map. This fact was substantiated by the several film badges located in Carp for the entire series. The maximum series dose indicated by a film badge in Carp, Nev., was 60 mr. The 1 r. infinite-dose contour crossed U. S. 93 at a nonpopulated place.

The maximum air concentration measured was $4.0\times10^{-2}\mu c/m^3$, at St. George, Utah. This represents the average air concentration for a 28-hour period starting at shot time.

TURK

Turk was a 500-foot tower detonation which was fired at 5: 20 a. m. on March 7, 1955. The detonation took place in test area 2 in Yucca Flat.

The airway-closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was closed at all altitudes from 5 a. m. to 9: 30 a. m.
2. An area southwest of the test site, bounded as described below, was ordered closed from 25,000 to 30,000 feet from 7 a. m. to 12: 30 p. m. From EH0000 due south to EG0000, then southwest to the east edge of airway Amber 1 at Bakersfield, then along the east edge of Amber 1 to AH0000, then due east to EH0000.
3. An area north and east of the test site, bounded as described below, was ordered closed from 32,000 feet up from 6: 30 a. m. to 12: 30 p. m. From EH 0000 on a bearing of 42° true for 320 nautical miles, then due south to JG4500, then due west to EG0000, then due north to EH0000.

At 10: 23 a. m. conditions were such that closure time in areas 2 and 3 was cut back to 11 a. m. instead of 12: 30 p. m.

The cloud was tracked as shown on the accompanying map from H plus 30 minutes to H plus 4 hours and 55 minutes. Tracking was performed by the following aircraft:

B–50: initially at 28,000 feet and subsequently at 31,000 and 25,000 feet.
B–29: 20,000 to 23,000 feet.
B–25: 11,000 to 14,000 feet.
Samplers (F–84): 36,000 to 42,000 feet.

Maximum cloud height observed was 42,500 feet. The wind pattern at shot time was such that the cloud became broken and dispersed in a very short time, with two general zones containing most of the cloud components. At altitudes up to about 28,000 feet, the cloud generally drifted into the northwest quadrant from GZ, with the maximum distance being approximately 85 nautical miles at 20,000 to 23,000 feet bearing from CP 315° true. The second zone was between 40° and 105° true at high altitudes (above 30,000 feet), extending to 105 nautical miles at 105° true and about 130 nautical miles at about 75° true. In many instances, the cloud appeared to have several different leading edges, and at times doubled back on its previous path.

A low-level terrain survey was flown on D-day by one C–47 from about H plus 6.5 to H plus 11. The fallout pattern indicated by this flight was quite scattered, and on D plus 1, additional flights were made by the C–47 and by a helicopter.

The pattern shown on the accompanying map was drawn using data from all three flights. It is evident that, just as the cloud-track pattern was widespread and, in several directions, so also was the fallout pattern.

Monitoring runs, which indicated activity substantially above background, were made along U. S. 93 in the vicinity of Pioche, Nev.; on Utah 21 between Beaver, Utah, and the Utah-Nevada State line; on U. S. 95 between Beatty, Nev., and Goldfield, Nev.; along Utah 15 in the Toquerville, Utah, area; along U. S. 6 between Tonopah, Nev., and Ely, Nev.; in the vicinity of Ely, Nev.; along Nevada 25 between Crystal Springs, Nev., and Warm Springs, Nev.; and on the desert roads northeast and west of the Nevada test site.

The maximum effective biological dose for a populated area was 157 mr. at Warm Springs, Nev. The maximum effective biological dose at a nonpopulated point was 30,500 mr. 15 miles west of Nevada test site on a desert road.

Approximately 220 individual monitoring readings above 0.1 mr./hr. were recorded.

A comparison of the prediction map and the factual maps indicates an extreme overprediction. This came about as a result of a frontal system change which occurred near shot time. This frontal change resulted in a drastic reduction in wind speeds and a rapid shifting of wind directions.

The ground-survey map shows the wide scattering of fallout under the meteorological conditions mentioned above. Also, the effects of terrain on the fallout pattern are quite pronounced. It is apparent from this map that the 1 r. isodose contour did not intersect any major highways.

The maximum air radioactivity concentration measured was $1.7\times10^{-3}\mu c/m^3$. at Currant, Nev. This represents the average air concentration for a 29-hour period starting three-quarters of an hour after shot time.

Hornet

Hornet was a 300-foot tower detonation which was fired at 5:20 a. m. on March 12, 1955. The shot took place in test area 3 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was closed at all altitudes from 5 a. m. to 9 a. m.
2. A sector, bounded by radii at 70° and 130°, length of radius 125 nautical miles, was ordered closed from 21,000 to 32,000 feet from 6:50 a. m. to 12 noon.

3. That part of the above sector extending between radial distances of 125 nautical miles and 200 nautical miles was ordered closed from 30,000 feet to 40,000 feet from 6 a. m. to 11:30 a. m.

4. At 9:15 a. m., the situation was such that sectors 2 and 3, above, were opened after 10:30 a. m.

The cloud was tracked at three levels: 10,000 to 14,000; 23,000 to 30,000; and 36,000 feet, by B-35, B-29, and sampler aircraft respectively. The track obtained is shown on the accompanying map. Maximum cloud height observed was 39,300 feet. The cloud was tracked to a distance of about 140 nautical miles from the CP, becoming so dispersed at this distance as to render further tracking impractical.

A low-level terrain survey mission was flown by one C-47 aircraft from H plus 6 hours and 40 minutes to H plus 11 hours. The fallout pattern obtained from the data reported is shown on the accompanying map. The fallout pattern was determined out to a distance of 100 nautical miles at which point low radiation levels made continuation impracticable.

Monitoring runs, which indicated activity substantially above background, were made on the game preserve road north of U. S. 95; on the Mormon Mesa road north of U. S. 91; on U. S. 91 between the Nevada-Utah State line and Glendale, Nev.; along U. S. 93 between Panaca, Nev., and Glendale, Nev.; on Nevada 12; on Nevada 40; along the desert road north of Indian Springs, Nev.; along the roads in the Moapa Indian Reservation; and on the desert roads just east of the Nevada test site.

The maximum effective biological dose for a populated area was 293 mr. at Glendale, Nev. The maximum effective biological dose at a nonpopulated point was 3,502 mr. 29.5 miles north of Indian Springs, Nev.

Approximately 300 individual monitoring readings above 0.1 mr/hr were recorded.

A comparison of the prediction map and the factual maps indicates good agreement in direction and relatively good agreement in magnitude. However, the 4 r. and 1 r. contours actually extended about 50 percent of the predicted distance. The ground survey map shows the results of directional shear which resulted in fallout in the Alamo, Nev., area. It also indicated the uneven isodose contours that may be expected, particularly at relatively low doses. It is apparent from the ground survey maps that the 1 r. isodose contour did not intersect any major highways.

The maximum air radioactivity concentration measured was 1.2 by 10^{-2} $\mu c/m^3$ at Glendale, Nev. This represents the average air concentration for a 28-hour period starting at shot time.

Bee

Bee was a 500-foot tower detonation which was fired at 5:05 a. m. on March 22, 1955. The shot took place in test area 7 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 4:45 a. m. to 5:30 a. m.
2. A sector as described below was ordered closed from 5:45 a. m. to 10:15 a. m. at altitudes from 17,000 to 40,000 feet. The boundaries of the sector were: From CP along 100° radius to LF 5745, then south to LD 4730, east to Phoenix, Ariz., then along north edge of airway Green 5 to FD 2740, and finally back to CP along 160° radius.
3. At 7:25 a. m. airway Amber 2 was closed at all altitudes within the above sector for 1 hour.
4. At 7:30 a. m. airway Red 15 was ordered closed at all altitudes between Amber 2 and Green 4 for 1 hour.
5. At 8:40 a. m. Amber 2 was opened at all altitudes.

The cloud was tracked by B–25, B–29, and sampler aircraft to a maximum distance of about 130 nautical miles on a general bearing of about 130°. The plot made from reports of these aircraft is shown on the accompanying map. The cloud stabilized at about 39,000 feet, and separated into several layers below the top altitude.

No D-day low-level terrain survey was made by the C–47 as ground parties were reporting fairly low intensities. On D-plus-one day, a survey was made to cover the areas inaccessible to ground parties. It was not possible to obtain reliable results from this survey because the cloud from Ess (detonated the day after Bee) drifted along virtually the same path as that from Bee, such that fallout from both shots would be expected in the same areas.

Monitoring runs, which indicated activity substantially above background, were made on U. S. 93 between Las Vegas, Nev., and a point 30 miles southeast of Boulder City, Nev.; along U. S. 91 between a point 2 miles northeast of Nellis Air Force Base and the intersection of South Fifth Street (Las Vegas proper); in North Las Vegas, Nev.; in the northeast section of Las Vegas, Nev.; on the game preserve road north of U. S. 95; along the desert road north of Indian Springs, Nev.; and on several of the desert roads east of the Nevada test site.

The maximum effective biological dose for a populated area was 185 mr. at North Las Vegas, Nev. The maximum effective biological dose at a nonpopulated point was 26,400 mr. 4.7 miles south of Papoose Lake.

Approximately 170 individual monitoring readings above 0.1 mr./hr. were recorded.

A comparison of the prediction map and the factual maps indicates rather poor agreement in direction and especially in magnitude. Fallout occurred south of the predicted path and the 1 r. infinite isodose contour extended out only about 20 percent of the predicted distance. It is apparent from the factual map that the 1 r. isodose contour did not intersect any major highways.

The maximum air radioactivity concentration measured was $3.5\times10^{-3}\mu c/m^3$, at Nellis Air Force Base, Nev. This represents the average air concentration for a 12-hour period starting at shot time.

Ess

Ess was an underground detonation which was fired at 12 p. m. on March 23, 1955. The shot took place in test area 10 in Yucca Flat.

No airway closure pattern was established for Ess.

The cloud was tracked as shown on the accompanying map from H plus 35 minutes to H plus 4 hours and 20 minutes. Tracking was accomplished between 10,000 and 13,000 feet by a B–25 type aircraft.

A low-level terrain survey was flown from H plus 3 hours to H plus 5 hours by 1 C–47. The results of this survey are shown on the accompanying map.

Monitoring runs, which indicated activity substantially above background, were made on U. S. 93 between a point 21 miles south of Alamo, Nev., and Glendale, Nev.; on the desert road north of Indian Springs, Nev.; and along several of the desert roads east of the Nevada test site.

The maximum effective biological dose for a populated area was 30 mr. at Beaver Dam, Ariz. The maximum effective biological dose at a nonpopulated point was 2,510 mr. 22 miles north of Indian Springs, Nev.

Approximately 105 individual monitoring readings above 0.1 mr./hr. were recorded.

A comparison of the prediction map and the factual maps indicates good agreement in direction, but the 1 r. isodose contour was at least twice as long as was predicted.

The low-level terrain survey map shows roughly twice the infinite doses that are plotted from ground monitoring results. The leading edge of the cloud did not cross the eastern boundary of the bombing and gunnery range until approximately H plus 4 hours. The haze from the cloud could still be seen in the Valley to the east and northeast of Indian Springs, Nev., at H plus 5 hours. The higher dose indicated by the low-level terrain survey are, therefore, probably due to radiation from that part of the cloud still in the valley when the survey was made. The ground monitoring plot also indicates extensive shear and the effects of terrain features on fallout pattern. It is apparent from the maps that the 1 r. isodose contour did not intersect any major highways.

The maximum air radioactivity concentration measured was $4.5\times10^{-3}\mu c/m^3$, at Mesquite, Nev. This represents the average air concentration for a 43-hour period starting 1.5 hours after detonation.

Apple

Apple was a 500-foot tower detonation which was fired at 4:55 a. m. on March 29, 1955. The shot took place in test area 4 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles was closed at all altitudes from 4:30 a. m. to 2 p. m. The extended closure time was necessary since a second shot, Wasp Prime, was scheduled for approximately 10 a. m.
2. A sector, with radii at 70° and 130° extending to the Utah-Colorado and Arizona-New Mexico borders, was closed from 22,000 feet and above from 6 a. m. to 1 p. m.
3. At 6:20 a. m., the closed altitudes were changed to read 18,000 to 33,000 feet, inclusive.
4. At 9:10 a. m., the 130° radius was moved to 110°, extending to the north edge of airway Green 4, and along this path to the Arizona-New Mexico border.

The cloud was tracked by one B–50 and one B–25 aircraft at the levels of 21,000 and 13,000 feet, respectively, with additional reports from sampler aircraft. The maximum distance to which the cloud was tracked was 166 nautical miles on a bearing of approximately 90°. At the lower level, the general bearing was between 60° and 70°. Maximum cloud height observed was 31,000 feet.

A low-level terrain survey was flown by one C–47 starting at about H plus 6 hours and 35 minutes. Results are plotted on the accompanying map.

Monitoring runs, which indicated activity substantially above background, were made on U. S. 91 between St. George, Utah, and Cedar City, Utah; along U. S. 93 between Alamo, Nev., and Pioche, Nev.; on Utah 18 between Central, Utah, and Beryl, Utah; along Utah 56 west of Cedar City, Utah, and continuing on Nevada 25 to the junction with U. S. 93; along Nevada 25 in the vicinity of Lincoln Mine, Nevada; on the desert road north of Indian Springs, Nev.; and along several of the desert roads north and east of the Nevada test site.

The maximum effective biological dose for a populated area was 1,300 mr. at Alamo, Nev. The maximum effective biological dose at a nonpopulated point was 6,500 mr., 4.3 miles south of Groom Lake on Kelly Mine Road.

Approximately 395 individual monitoring readings above 0.1 mr./hr. were recorded.

A comparison of the prediction map and the factual maps indicates that the predicted direction was off by 20° and that the 1 r. infinite isodose contour extended only about one-third of the predicted distance. The low-level terrain survey map is in good agreement with the map depicting ground monitoring results. The 1 r. infinite dose contour crossed U. S. 93 at Alamo, Nev.

The maximum air radioactivity concentration measured was $4.0 \times 10^{-3} \mu c/m^3$, at Alamo, Nev. This represents the average air concentration for a 28-hour period starting at shot time.

Wasp Prime

Wasp Prime was an airdrop which was detonated at 10 a. m. on March 29, 1955. The shot took place in test area 7 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 4:30 a. m. to 2 p. m. This was in conjunction with the flash circle for Apple.
2. A sector, with radii at 50° and 110°, length of radius 150 nautical miles, was ordered closed from 15,000 to 35,000 feet from 1 a. m. to 4 p. m.

3. At 10:30 a. m., the flash circle was opened between 110° and 360°. The end closure time on the sector and remaining part of the circle was changed to 1 p. m.

4. At 10:55 a. m., the lower closed altitude was raised from 15,000 to 18,000 feet.

A C–45 aircraft was assigned to track the cloud as the B–25 used earlier in the day for Apple was contaminated. The aircraft developed engine trouble and aborted the mission. A second C–45 was dispatched and tracked the cloud at 10,000 feet. Normal procedure could not be followed since the C–45 was not capable of flying at sufficiently high altitudes. In place of normal procedure, the cloud was tracked visually from below by the tracking aircraft. Additional reports were submitted by sampler aircraft. At low levels, the direction of the cloud track was along a bearing of 55° to 60°, while at higher levels, the approximate bearing was 74°. The maximum distance to which the track was followed was about 70 nautical miles.

No separate monitoring, either air or ground, was conducted for this detonation for two reasons. First, no fallout was expected and, secondly, as the cloud tracks were essentially the same in direction, any fallout would be determined by normal operational monitoring for Apple. Thus, the low level terrain survey and the ground monitoring maps for Apple are labeled "Apple and Wasp Prime Combined."

HA

HA was an air detonation which was fired at 10 a. m. on April 6, 1955, at an altitude of approximately 36,000 feet. The shot took place over Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 8:30 to 1 p. m.

2. A sector with a radii at 110° and 180°, length of radius 150 nautical miles, was ordered closed from 25,000 feet up from 10 a. m. to 1 p. m.

3. At 11 a. m., all restrictions were removed.

Due to the height of the detonation, no regular cloud-tracking missions were flown. At 10:12 a. m. the cloud height was estimated by the sampler control aircraft to be 55,000 to 60,000 feet. Later data, at 10:20 a. m., indicated a drop to 45,000 to 47,000 feet.

No low level terrain survey missions were flown as no fallout was reported from ground monitoring teams.

Monitoring runs, made in the off-site area, indicated only background.

The only air radioactivity concentration measured in excess of $10^{-4}\mu c/m^3$ was $1.35\times10^{-4}\mu c/m^3$, at Lincoln Mine, Nev. This represents the average air concentration for a 24-hour period starting at shot time.

Post

Post was a 300-foot tower detonation which was fired at 4:30 a. m. on April 9, 1955. The shot took place in test area 9 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 4 a. m. to 11:30 a. m. The extended closure time was due to the scheduling of another detonation, Met, later in the morning.

2. At 6:10 a. m., closure time on the flash circle was extended to 2 p. m. due to a delay in possible firing of Met.

3. At 8:10 a. m., closure time was cut back to 9 a. m. due to cancellation of Met.

The cloud was tracked by 1 B–25 aircraft flying at 13,000 feet, with additional reports coming from sampler aircraft. Maximum cloud height observed was 15,000 feet, with subsequent settling to 14,500 feet. The cloud was tracked to a maximum distance of 36 nautical miles at a bearing of approximately 165° from the command post. The plot of the cloud track is shown on the accompanying map.

A low level terrain survey was made by 1 C–47 aircraft from approximately H plus 5 hours to H plus 7 hours and 15 minutes. The survey indicated no significant off-site contamination.

Monitoring runs, which indicated activity substantially above background, were made on Mercury Road; along U. S. 95 between Lathrop Wells, Nev., and Indian Springs, Nev. on Nevada 16 between U. S. 95 and U. S. 91; and on the desert roads north and east of the Nevada test site.

The maximum effective biological dose for a populated area was 47 mr. at Camp Desert Rock, Nev. The maximum effective biological dose at a nonpopulated point was 162 mr., 3.5 miles south of Papoose Lake.

Approximately 75 individual monitoring readings above 0.1 mr/hr. were recorded.

The ground survey map indicates extensive scattering of fallout in several directions. An interesting point is the presence of fallout to the northeast, although the cloud was tracked in a southerly direction. Only very light fallout occurred outside the Nevada test site.

The maximum air radioactivity concentration measured was $9.0 \times 10^{-1} \mu c/m^3$, at Indian Springs, Nev. This represents the average air concentration for a 17.5-hour period starting at shot time.

MET

Met was a 400-foot tower detonation which was fired at 11:15 a. m. on April 15, 1955. The shot took place in Frenchman Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 10:30 a. m. to 4 p. m.
2. A sector, with radii at 40° and 100°, length of radius 200 nautical miles, was ordered closed from 15,000 to 20,000 feet from 11 a. m. to 4 p. m.
3. A continuation of and including this sector, extending northeast to JL 2049 then southeast to the Arizona-New Mexico border at LG 4700, then west to KG 5000, then northwest along 100° radius to sector 2, above, was closed from 21,000 to 42,000 feet from 11 a. m. to 8 p. m.
4. An area from JL 2049 along the southern edge of airways Red 49 and Green 3 to Medicine Bow, then along the western edge of Green 3 to Denver, continuing along the western boundaries of Denver and the western edge of Amber 3 to Colorado Springs, and finally southwest to LG 5700 was ordered closed from 25,000 to 42,000 feet from 2:30 p. m. to 8 p. m.
5. At 12 noon, the top altitude in 3 and 4 above was changed from 42,000 feet to 44,000 feet, and the beginning closure time in 4 above was moved back to 2 p. m.
6. At 12:30 p. m. the bottom altitude in sector 2 above was lowered to 10,000 feet.
7. At 2:50 p. m., the flash circle was opened except that portion in sector 2 and the lower altitude in sectors 2 and 3 was raised to 21,000 feet effective at 3:15 p. m.
8. At 4 p. m., area 4 was reduced by opening the area south of airway Victor B effective at 4:15 p. m.

The cloud was tracked by one B–25, two B–50's, and sampler aircraft. Maximum cloud height observed was 42,800 feet, settling quickly to 41,300 feet. Base of the mushroom was reported at 28,000 feet. The cloud was tracked to a maximum distance of 200 nautical miles on an approximate true bearing of 65° from the C. P. In general, all levels (13,000, 23,000, 28,000, and 42,000 feet) tracked followed the same bearing.

A low-level terrain survey was made by one C–47 aircraft from approximately H plus 3 hours and 15 minutes to H plus 7 hours. The fallout pattern is plotted on the accompanying map. Due to the relatively late detonation time, the aerial survey had to be cut short, as the aircraft could not conduct the low-level survey after sunset. For this reason, sufficient data to close the 1 r. infinite dose contour was not obtained.

Monitoring runs, which indicated activity substantially above background, were made along U. S. 93 between 36 miles north of Glendale, Nev., and the junction of Nevada 25; on Utah 21 between Beaver, Utah, and 7 miles west of Milford, Utah; on U. S. 91 between 5 miles north of Cove Fort, Utah, and Parowan, Utah; along Nevada 25 and Utah 56 between U. S. 93 and Newcastle, Utah; along Nevada 55 between 4 miles south of Elgin, Nev., to Caliente, Nev.; on Utah 18 between Enterprise, Utah, and Beryl Junction, Utah; along Utah 98 from Beryl Junction, Utah, to Beryl, Utah; on Utah 19 between Lund, Utah, and the junction of Utah 56; on the desert road north of Indian Springs, Nev.; along the game preserve road north of U. S. 95; and on several other desert roads northeast of the Nevada test site.

The maximum effective biological dose for a populated area was 2,880 mr. at Elgin, Nev. The maximum effective biological dose at a nonpopulated point was 44,600 mr. 24 miles north of Indian Springs, Nev.

Approximately 340 individual monitoring readings above 0.1 mr./hr. were recorded.

In general, all the maps are in good agreement as to both direction and magnitude. The actual 1 r. infinite isodose contour was a few miles longer than predicted, terminating northeast of Utah 21 rather than southwest. It is apparent that the 10 r. infinite isodose line crossed U. S. 93 southeast of Alamo, Nev.

The maximum air radioactivity concentration measured was $6.1\times10^{-2}\mu c/m^3$, at Beaver, Utah. This represents the average air concentration for a 24.8-hour period starting at shot time.

APPLE TWO

Apple Two was a 500-foot tower detonation which was fired at 5:10 a. m. on May 5, 1955. The shot took place in test area 1 in Yucca Flat.

The airway closure pattern was as follows:

1. A circular area around Yucca Flat, with a radius of 60 nautical miles, was ordered closed at all altitudes from 4:45 a. m. to 9:30 a. m. The southern half of this circle was to be opened at H plus 10 miutes.
2. A sector, radii at 315° and 20°, length of radius 140 nautical miles, was closed from 14,000 to 24,000 feet from 6:30 a. m. to 9 a. m.
3. A sector, radii at 335° and 30°, length of radius 200 nautical miles, was closed from 24,000 to 44,000 feet from 6 a. m. to 10 a. m.
4. A continuation of this sector 3, above, extending the radius to 400 nautical miles, was closed from 24,000 to 44,000 feet from 8:30 a. m. to 12 noon.
5. At 6:30 a. m. the 30° bearing in sectors 3, and 4, was changed to 50°, and the extreme length of radius was reduced to 300 nautical miles.
6. At 8 a. m. the end closure time in 3. was changed to 12 noon, and the start closure time in 4. was changed to 9 a. m.
7. At 10:10 a. m., sector 4. was opened at all altitudes.

Cloud track data were received from one B–25, two B–50's, and sampler aircraft. Maximum cloud height observed was 40,500 feet. Considerable shear was present and the various levels tracked showed a spread in bearing from about 340° to 60°. The cloud was tracked to a miximum distance of about 120 nautical miles at all levels. The plot of the several tracks is shown on the accompanying map.

A preshot survey was flown on D–3 days since the zone of predicted fallout was in a direction not extensively surveyed by air previously. A low level terrain survey was flown by one C–47 aircraft from H plus 5 hours to approximately H plus 10 hours and 30 minutes. Results of this survey are plotted on the accompanying map.

Monitoring runs, which indicated activity substantially above background, were made along U. S. 93 between 45 miles north of Pioche, Nev., and Ely, Nev.; on Nevada 25 between U. S. 6 and several miles west of Lincoln Mine, Nev.; on U. S. 6 between 1 mile east of Warm Springs, Nev., and Ely, Nev.; along Nevada 20 between Currant, Nev. and U. S. 50; on U. S. 50 between 55 miles west of Eureka, Nev., and Nevada 73; along Nevada 73 between U. S. 50 and Nevada 21; on Utah 21 between Nevada 73 and 25 miles east of Garrison, Utah; along Nevada 38 between Sunnyside, Nev., and 3 miles south of Sunnyside, Nev.; and along several of the desert roads north of the Nevada test site.

The maximum effective biological dose for a populated area was 2,580 mr. at Reed, Nev. The maximum effective biological dose at a nonpopulated point was 6,270 mr. in Kawich Valley northwest of the Nevada test site.

Approximately 385 individual monitoring readings above 0.1 mr/hr., were recorded.

A comparison of the prediction map and the factual maps indicates good directional agreement with an overprediction in magnitude (length of isodose contours). The cloud track map shows one reason for the overprediction, and that is shear. The cloud was dispersed to a great extent laterally. The ground survey infinite dose map shows the 1 r. contour crossing U. S. 6 about midway between Tonopah and Ely, Nev. The shear, previously mentioned, is also evident in the construction of the isodose lines.

The maximum air radioactivity concentration measured was 5.9×10^{-2} $\mu c/m^3$, at Ely, Nev. This represents the average air concentration for a 28-hour period starting at shot time.

Zucchini

Zucchini was a 500-foot tower detonation which was fired at 5 a. m. on May 15, 1955. The shot took place in test area 7 in Yucca Flat.

The airway closure pattern was as follows:

1. Starting the evening of May 14 at 10:11 p. m., the warning circle was set up as a 265-nautical-mile radius at the Grand Canyon Airport. The flash circle was a standard 60-nautical-mile radius of the coordinates 37° N. 116° W. and closed at all altitudes from 4:30 to 9:30 a. m. The low-level closure was between the bearings of 140° and 180° for a distance of 120 nautical miles and closed at the altitudes from the surface through 13,000 feet. The time of closure was 6:30 a. m. to 9 a. m. The middle-level closure was between bearing lines of 100° and 180°, determined by extending the 180° line for 150 nautical miles and extending the 100° line for 340 nautical miles with an arc of 340-nautical-mile radius drawn off the 100° bearing; then at a distance of 150 nautical miles on the 180° line, a direct line extending through the Phoenix low-frequency radio range station to intersect the 340-nautical-mile arc. The first segment of the middle level was the area extending from the test site out 150 nautical miles. This area was closed at 13,000 feet through 23,000 feet, inclusive. The time of closure was 5:45 a. m. to 10 a. m. The second segment was all the area between 150 nautical miles and 340 nautical miles and closed at the altitudes of 16,000 to 23,000 feet, inclusive, from 7:15 a. m. to 10 a. m. The high-level closure was between the bearings of 50° and 140°. The 140° line was extended to intersect the north edge of airway Green 4, then direct to the 4 corners, direct to the Grand Junction low-frequency-range station. The 50° line was extended across the east course of the Delta, Utah, radio-range station and direct to Grand Junction. The first segment of the high-level closure was all the area west of a line drawn from Delta to the Grand Canyon Airport. The altitudes closed were 23,000 to 40,000 feet from 5:30 to 8:45 a. m. The second segment was all the area east of the Delta-Grand Canyon line and closed at the altitudes of 23,000 to 40,000 feet from 6:45 a. m. to 12 noon.
2. At 6:07 a. m., tracking aircraft reports indicated the low-level trajectories had changed, and the 140° and 180° bearing lines were changed to read 100° and 140°. The closure time remained the same.
3. At 6:26 a. m., the middle-level closure was changed to correspond with the high-level closure. This area was then closed at the altitudes of 13,000 to 40,000 feet, inclusive.
4. At 7:05 a. m., the combined high- and middle-level areas were extended from Delta, Utah, directly to the south edge of airway Green 3 at Fort Bridger, Wyo., then east along the south edge of airway Green 3 to Medicine Bow, then south along the west edge of Green 10 to Denver, then west to the north edge of airway Victor 8 to Grand Junction.
5. At 8:26 a. m., closures remaining effective at 9 a. m. were the second segment of the high- and middle-level closure lying east of the Delta-Grand Canyon line. This area was then closed at altitudes 20,000 to 40,000 feet, inclusive, from 9 a. m. to 12 noon. All tracking aircraft were returned to base and no further changes were made.

The cloud was tracked by 1 B-25 at 13,000 feet, 2 B-50's at 23,000 and 28,000 feet, respectively, and by sampler aircraft at approximately 35,000 feet. Maximum cloud height reported was 37,700 feet, stabilizing at 36,300 feet. The cloud was tracked by the B-50's and sampler aircraft on an approximate bearing of 69° for a distance of 218 nautical miles. The low-level portion was followed 145 nautical miles on a 118° bearing.

A low-level terrain survey was made by 1 C-47 aircraft from H plus 5 hours and 30 minutes to H plus 10 hours and 30 minutes. The accompanying map shows that fallout occurred along an approximate bearing of 105°.

Monitoring runs, which indicated activity substantially above background, were made along Utah 18 from 3 to 38 miles south of Enterprise, Utah; on U. S. 91-93 from Glendale, Nev., to 4 miles south of Apex, Nev.; along U. S. 91 from Glendale, Nev., to Paragonah, Utah; along U. S. 93 from Glendale, Nev., to 38 miles north of Glendale; on Warm Springs Ranch, Nev., Road; along the Mormon Mesa Road; on the roads in the Moapa Indian Reservation; on Nevada 40; on Nevada 12; and along several of the roads east of the Nevada test site.

The maximum effective biological dose for a populated area was 700 mr. at Moapa, Nev. The maximum effective biological dose at a nonpopulated point was 19,900 mr., 7.5 miles south of Papoose Lake.

Approximately 375 individual monitoring readings above 0.1 mr./hr. were recorded.

A comparison of the prediction map and the factual maps indicates an over-prediction in magnitude and a 5° to 10° difference in direction. The low-level terrain survey map shows good agreement with ground survey results with the exception that it indicates shorter isodose lines. The ground survey map shows an additional light fallout pattern to the northeast. One r. infinite isodose contour intersected U. S. 91 and U. S. 93 in the vicinity of Glendale, Nev.

The maximum air radioactivity concentration measured was 7.8×10^{-6} $\mu c/m^3$, at Cedar City, Utah. This represents the average air concentration for a 28.2-hour period starting at shot time.

6. SUMMARIES

In this section are summaries of the film badge program, accumulated dosage in populated areas, water and milk results, and air results. Each of these subjects is discussed in a subsection while accumulated dosage in populated areas is presented as table 2. The values presented are those measured by survey instruments and by film badges. Survey instrument readings have been expressed as effective biological dose and as infinite dose. Every populated place in which either type measurement was made is included.

FILM BADGE PROGRAM

Film badges have proved to be a practical method for large-scale area monitoring. During Operation Teapot, an area of approximately 50,000 square miles was effectively monitored by the use of film badge stations. These stations consisted of the following categories: 171 worn by residents in the off-site area; 106 in populated areas; 152 inside and outside schools; and 126 at nonpopulated points along all of the major highways and most of the less-traveled roads. Badges were changed at frequent intervals, with a total of 4,420 individual badges used during the operation.

These data are summarized in five bar graphs, V through IX. In these graphs, the percentage of accumulated exposures for the test period which fall into various arbitrary exposure classifications are plotted. The actual number of stations which occur in a particular exposure interval are written into the bar and the highest accumulated exposure for a single station within a category is indicated on the graph.

Graph V shows the accumulated dosages received by the 171 individuals scattered throughout the area who wore film badges. There were only 3 individual exposures greater than 500 mr for the test period. All of these occurred in Alamo and the highest was 750 mr. Since the records show that a portion of this dose may have been accumulated in Kawich Valley, it is more likely that the exposure at Alamo was around 600 mr.

Graph VI shows the accumulated exposure as measured in populated areas other than on people. The range of exposures and the upper limit is greater than is shown on personnel badges. The highest single accumulated exposure was 3,910 mr at Elgin, Nev.

A comparison of graphs V and VI seems to indicate that the dosage received by the inhabitants of a particular area is less than the dose indicated for that area as measured by the same method. Approximately 94 percent of the dosages measured on people were within the 0 to 100 mr range and only about 57 percent of the exposures measured in these same areas were within this range.

Graph VII shows the accumulated exposure measured in unpopulated areas. Although there are a greater number of higher exposures noted in this category, this is a reflection of the higher close-in readings. Levels greater than 3,900 mr were detected at only one station beyond the gunnery range limits. This was an accumulated exposure for the test period of 6,930 mr at an uninhabited point on U. S. 93, 15 miles south of Alamo.

ARBITRARY EXPOSURE INTERVALS IN M.R.

Graphs VIII and IX show the accumulated exposures outside and inside of schools, respectively. The highest exposure outside was 1,160 mr at Alamo and the highest inside exposure noted was at Fallini Ranch School. The significant feature of these graphs is the apparent protection afforded by school buildings. The upper exposure limit is reduced by a considerable factor on a gross basis and while about 95 percent of the inside exposures fall within the 0–100 mr range, only about 77 percent of the outside badges are so limited.

One other factor of interest should noted. When the badges are considered on an individual basis rather than by stations for the whole period, the percentage of negative badges becomes very large. The entire range of percentages for individual badges is tabulated below.

If one considers the extensive area covered during Operation Teapot, the total number of badges and the large number of badge stations, and the numbers of people wearing badges off site, then film badge monitoring would appear to have the following desirable characteristics:

1. Film badges offer a permanent record of accumulated radiation exposure.
2. The exposure measurements obtained from film badges are not subject to error due to mathematical manipulation.
3. Film badges are convenient to use.
4. Extensive areas can readily be monitored by the use of film badges.
5. Film badges require no attention during the time they are recording radiation exposure.
6. From all available information, it appears that film badges can be left in the field for extended periods without adversely affecting the accumulated exposure data obtained.
7. People wearing film badges have a positive feeling that steps are being taken to look after their welfare. The typical attitude seemed to be twofold: (*a*) that they were important enough to be considered; and (*b*) the feeling of being protected.
8. Film badge records have an official status in radiation protection programs.

Based on performance during Operation Teapot, film badges are an effective, practical, and economical way to monitor both extensive land areas and people during a continental test series.

Inevitably, when data which presumably measure the same thing are collected, a comparison of results seems indicated. Comparative data at film badge stations in the Lincoln Mine zone are shown in the following table for illustrative purposes. The results shown are given in terms of effective biological dose, infinite dose, and accumulated dose as measured on film badges.

If one were to draw conclusions, these could only be broad generalizations, such as that the film dosage is *roughly comparable to the effective biological dose*. Striking exceptions are apparent. To attempt to be more specific, as for example, trying to arrive at a valid, constant factor relating the various types of data is not warranted. The reasons for this are outlined below. All of these various data, however, are useful and the fact that they cannot be strictly correlated does not impair their individual value for various purposes.

Film badges and monitoring data do not measure exactly the same thing although it might seem so at first glance. The measurements made by these various methods might be stated as follows:

Film badge results are a measure of the total accumulated radiation exposure within a given energy range, at a fixed point, and for a given time interval. This time is generally the period of the test series plus a week or two prior to and after the series.

Comparison of accumulated dosage readings in the Lincoln Mine area

Film badge station	Monitoring results		Film badge dose, milli-roentgen	Film badge station	Monitoring results		Film badge dose, milli-roentgen
	Effective biological dose, milli-roentgen	Infinite dose, milli-roentgen			Effective biological dose, milli-roentgen	Infinite dose, milli-roentgen

Infinite dose is the maximum calculated exposure from time of fallout to infinite time at the place of measurement, based on an instrument reading taken at that place and extrapolated to infinity.

Effective biological dose is a percentage of the infinite dose obtained by inserting certain impirical factors for shielding, weathering, etc.

The reasons why these various means of estimating accumulated dose are not absolutely comparable are:

1. Both EBD and film badge doses are a variable percentage of the infinite dose. The relationship of EBD to infinite dose varies from approximately 60 percent when the time of fallout is 30 minutes to about 50 percent when the time of fallout is 9 hours. The relationship of film badge exposure to infinite dose varies with the total time interval covered by the film badge series, at a particular point.
2. Infinite dose and EBD are mathematical extrapolations of a single reading by instruments, which will vary with the accuracy of the reading and the approximation of fallout time.
3. Dosage determination by film badge measurements does not require a knowledge of fallout time. Film badges measure directly the actual dose present at a point during the time of exposure If changes in radiation level occur during this time, such as the blowing away or covering up of radioactive material or the secondary deposition of radioactive material at a later time, these changes are reflected in the film badge readings but not in the infinite dose or EBD results.
4. When two closely spaced shots proceed in the same direction, the monitoring readings from the second shot may reflect residual radioactivity from the previous shot. Extrapolation of the readings may result in higher infinite dose and EBD.
5. Fallout patterns are directional and frequently sharply defined within a given area. Unless the monitoring reading is taken at the exact point of film badge exposure, the results cannot be compared.
6. It is possible to fail to record a significant portion of the total exposure on film badges by discontinuing the program too soon. This would only occur under special circumstances. These would be a situation in a close-in area where the major portion of the exposure occurred on the last shot and the badges were collected immediately thereafter. It could be theoretically possible to fail to record several hundred mr. of total exposure under these conditions. It does not appear, however, that this could be too much of a factor beyond the gunnery range limits.
7. Film badges are a positive means of measurement of personnel exposure, Where film badges are worn by people, they measure the actual dose received as these people move about in their daily routine. As far as the individual's exposure is concerned, it is unnecessary to speculate as to his probable location to know his exposure, as is necessary when using monitoring measurements.

The above material indicates that monitoring and film badge measurements are both necessary and supplementary data. The overall picture of the total ex-

posure resulting from either type of data is similar in nature, but it is impractical to attempt to relate the two types of measurement through some specific and constant factor or factors.

The large amount of data that can be obtained with relative ease and economy by film badge measurements indicates that these measurements should become a permanent part of offsite planning. The major change that should be instituted is to increase the area coverage (school and personnel coverage was probably adequate) and at the same time to reduce the workload by less frequent badge changes.

Although the offsite program was concerned primarily with exposures of people and animals, numerous close-in monitoring runs were made to aid the Fallout Prediction Unit. In future operations, this assistance could be supplemented by lines of film badges across the gunnery range to aid in this objective.

Aside from the items mentioned above, and minor details regarding recordkeeping, the film badge program as operated was so successful and so productive that it appears that future programs should be based on the same general plan.

[2] A badge is missing, which may have added significantly to the total dose.

WATER AND MILK RESULTS

In tables 3 and 4 are presented selected results from radioactivity analysis of water and milk, respectively. The data are selective in that only results where the radioactivity concentration exceeded 10^{-5} μc/ml. at the time of collection are shown. During the series, a total of 149 water and 134 milk samples were processed.

The background concentration for water was 6.8×10^{-7} μc/ml. This average is based on the analysis of 30 samples. The background concentration for milk,

as determined from 21 samples was 1.8×10^{-6} μc/ml. These background samples were collected and analyzed prior to the start of the test series and the data presented are gross values.

Relative information can be obtained by comparing the respective background value with the data presented in the appropriate table. However, there are several factors which should be understood before making such a comparison. Such factors would include:

1. Background values are gross figures. In other words, there may be differences in background from one type source to another and from one area to another.
2. Extrapolation by the 1.2 decay law is not completely valid as radioactive materials are removed from water selectively and similar selectivity takes place when radioactive materials are metabolized by an animal. Therefore, the tabulated values are in all probability conservative.
3. Time of fallout in large lakes and running streams is difficult to determine.
4. Time of fallout as well as time and method of contamination for use in calculations involving milk samples is practically impossible to determine without exhaustive specialized study.

AIR RESULTS

Table 5 is a summary of all the air analyses obtained during Teapot. The location of air samplers, the dates and times of sampler operation, and the radioactivity concentration expressed as $\mu c/m^3$. averaged over the sampling period are given for each detonation. Values of 10^{-6} $\mu c/m^3$. and less are in the range of normal air-radioactivity backgrounds measured before and during the operation. Therefore, results less than 10^{-6} $\mu c/m^3$. are not listed other than as 10^{-6} $\mu c/m^3$.

APPENDIX

PERSONNEL

A total of 66 Public Health Service men were assigned to this operation for various periods of time. PHS personnel were composed of two categories, regular PHS personnel, and Reserve personnel who were called to active duty for the purpose of assignment to this operation.

The regular PHS personnel and their normal affiliation are as follows:

Anderson, E. C., Assistant Chief, radiological health program
Bevis, Herbert A., radiological health program, Washington, D. C.
Brewer, Lial W., occupational health field station, Salt Lake City
Butrico, Frank A., DHEW, region 2, New York, N. Y.
Carter, Melvin W., PHS, offsite program, Nevada test site
Coleman, Richard D., radiological health program, Salt Lake City
Ernsberger, Edward L., PHS, Rockville, Md.
Fooks, Jack H., DHEW, region 8, Denver, Colo.
Hagee, G. Richard, Robert A. Taft Sanitary Engineering Center, Cincinnati
Henderson, Paul C., DHEW, region 3, Washington, D. C.
Holaday, Duncan A., occupational health field station, Salt Lake City
Ingraham, Samuel C., M. D., National Cancer Institute, NIH, Bethesda, Md.
Kusnetz, Howard L., occupational health field station, Salt Lake City
Longaker, Ralph K.,DHEW, DESE, Washington, D. C.
Macomber, Ronald G., DHEW, region 2, New York, N. Y.
Mills William A., radiological health program, Washington, D. C.
Minken, Joseph L., CDC, Mount Vernon, N. Y.
Placak, Oliver R., officer in charge, PHS offsite program, Nevada test site
Powell, Clinton C., M. D., National Cancer Institute, NIH, Bethesda, Md.
Rechen, Henry J. L., radiological health program, Washington, D. C.
Schreeder, William B. DHEW, region 9, San Francisco, Calif.
Seal, Morgan S., radiological health program, Washington, D. C.
Soneda, Shinji, Robert A. Taft Sanitary Engineering Center, Cincinnati
Stangler, Marlow, Robert A. Taft Sanitary Engineering Center, Cincinnati
Terrill, James G., Jr., Chief radiological health program, Washington, D. C.

The Reserve personnel who were called to active duty, with the designation of their normal affiliation, are listed below:

Alabama:
  Habel, John C., Jefferson County Health Department, Birmingham
  Thomas, Fred W., USTVA, Wilson Dam
Arkansas: Wilson, Edward F., Arkansas State Board of Health, Little Rock
California:
  Ausseresses, W. M., Southern Pacific Railroad, San Francisco
  Brewer, Robert, State department of health, San Bernardino
  Stone, Ralph N., consulting engineer (civil), Los Angeles
  Vaden, John D., Los Angeles County Health Department, Los Angeles
Colorado:
  Newman, Edison E., State Health Department, Denver
  VanNattan, W. R., State Health Department, Denver
Connecticut:
  Bertran, Albert E., State Health Department, Hartford
  Herlihy, James F., City Health Department, Hartford
  Holt, John A., City Health Department, Hartford
Florida: Greenley, John W., Dade County Health Department, Miami
Georgia: Fetz, Richard H., State Health Department, Atlanta
Hawaii: Woo, Francis H., Department of Health, Hilo
Idaho:
  Cotton, Charles E., State Health Department, Boise
  Despain, Carroll E., City-County Health Department, Boise
Illinois:
  Bullock, Harrison E., State Health Department, Carbondale
  Kaufmann, Oliver W., University of Illinois, Urbana
Indiana: Wraight, Frank D., State Health Department, Indianapolis
Kansas: Rucker, Vernon L., Santa Fe Railroad, Topeka
New Jersey:
  Baker, Walter C., New Jersey Neuropsychiatric Institute, Princeton
  Berry, Clyde M., Esso Standard Oil Co., Linden

New Mexico: Jensen, Carl R., State Health Department, Santa Fe
New York: Marchese, Anthony S., State Highway Department, Poughkeepsie
North Carolina:
- Ameen, Joseph S., State Health Department, Raleigh
- Long, William N., Gaston County Health Department, Gastonia
- Seagle, Edgar F., State Health Department, Raleigh
- Sharpe, Thomas J., District Health Department, Hickory
- Williams, Giles M., State Department of Agriculture, Raleigh

North Dakota: Olson, Otmar O., District Health Department, Williston
Oklahoma:
- Harris, Carroll F., Oklahoma A. and M., Stillwater
- Pummill, Lloyd F., State Health Department, Oklahoma City

Oregon: Bower, William F., State Health Department, Portland
Tennessee:
- Brockett, Thomas W., Oak Ridge National Laboratory
- Davidson, Charles M., USTVA, Chattanooga
- Harless, Bennett L., Oak Ridge National Laboratory

Texas: Ledbetter, Joe O., State Highway Department, Weatherford
Vermont: Gilbert, Wilfred C., State Highway Department, Montpelier
Washington:
- Gregg, George O., State Department of Health, Chehalis
- Ruppert, Edwin L., State Department of Health, Seattle

Abbreviations and Nomenclature

CP—Control point, located in Yucca Pass between Frenchman and Yucca Flats.
GZ—Ground zero, the point above which a device is detonated.
hr—Hour.
mr—milliroentgen.
r—roentgen.
D-day—The day of a particular detonation.
H—The hour of exact time of a particular detonation.
U. S.—Refers to a specific highway.
uc—microcuries.
m^3—Cubic meters.
N—North.
E—East.
S—South.
W—West.
Mi.—Miles.
NTS—Nevada test site.
Times—Pacific standard time through 2 a. m. April 24, 1955; thereafter, Pacific daylight standard time.
EBD—Effective biological dose as defined in the DBM criteria.
AEC—Atomic Energy Commission.
PHS—Public Health Service.
CAA—Civil Aeronautics Administration.
ml—Milliliter.
Co^{60}—An isotope of cobalt having the mass number 60.
MSA—Mine safety appliance.
Sr^{90}—An isotope of strontium having the mass number 90.
Y^{90}—An isotope of yttrium having the mass number 90.

The following system of terminology is used when presenting data concerning airway closure patterns, cloud tracking, and low-level terrain surveys:

1. All elevations are given in terms of mean sea level unless otherwise stated.
2. All bearings are given in terms of true bearings unless otherwise stated.
3. In giving locations, the Georef coördinate system has been used for simplicity. In this system, a group of 4 letters and 4 numbers locates any given point. In the area of concern to this report, the first two letters, EJ, are common to all locations and are omitted for the sake of brevity. Of the second group of two letters, the first letter denotes longitude and the second latitude, according to the following table:

Georef letter	Longitude	Georef letter	Latitude
A	120°00′W.		
B	119°00′		
C	118°00′	C	32°00′N.
D	117°00′	D	33°00′
E	116°00′	E	34°00′
F	115°00′	F	35°00′
G	114°00′	G	36°00′
H	113°00′	H	37°00′
J	112°00′	J	38°00′
K	111°00′	K	39°00′
L	110°00′	L	40°00′
M	109°00′	M	41°00′
N	108°00′	N	42°00′
P	107°00′	P	43°00′
Q	106°00′		

Similarly, the 2 groups of 2 members each denote, respectively, minutes of longitude and minutes of latitude within the 1° quadrangle specified by the letter group. To provide an example, the coordinates of Las Vegas are EG 5120.

The identification of the 15° quadrangle (EJ) is omitted for the reason previously stated.

EG identifies the 1° quadrangle.

51 identifies the Georef minute of longitude.

20 identifies the Georef minute of latitude.

Radiation Exposures Received on Populated Atolls as a Result of Operation Redwing

During Operation Redwing 4 gamma intensity readings daily were taken at populated off-site atolls utilizing a radiac meter AN/PDR-27F, calibrated against a standard consisting of 7 micrograms of radium. Following each test, hourly readings were taken for an interval of time dependent upon fallout forecasts, wind conditions at and following test time, cloud tracking, and readings obtained at the atolls. The attached tables and charts show the weighted daily averages of these readings for the atolls at which stations were maintained.

An estimated cumulative exposure of the populations of these atolls resulting from Operation Redwing has been computed based on these meter readings. Net readings (above preoperation background) have been utilized. Where a residual radiation remained at the time the stations were inactivated, the 70-year exposure due to this residual was computed based on the equation $I_2T_1^{-k}=I_1T_2^{-k}$. Based on available decay data, k=1.2 was utilized. It will be noted that the last day's reading at Ujelang was 1.5 mr/hr. This was due to the test of July 21. The complete record shows that fallout had stopped and radiation intensities were decreasing at the time the station was inactivated. A reduction factor to determine effective biological dose was not utilized as conditions under which the natives live are not believed to warrant the commonly accepted reduction factor. Computations involved are attached. On this basis, 70-year external gamma doses resulting from Operation Redwing are as follows:

Ujelang Atoll: 560 mr.
Utirik Atoll: 53 mr.
Wotho Atoll: 616 mr.
Rongerick Atoll: 853 mr.

Also attached is a plot showing AN/PDR-27F readings at JTF-7 Headquarters, Parry Island, during the period July 21 to July 23, 1956. On the basis of these figures, effective external gamma doses to various periods of time have been computed as follows:

H+5 days: 3.45 R.
H+15 days: 5.7 R.
H+1 year: 7.95 R.
Infinity dose: 12.45 R.

Computations are attached.

DOSE CALCULATIONS FOR PARRY ISLAND

Accumulated dose to 220700 M was 0.6R
At that time decay started with the decay constant $K=-1.2$
Personnel leaving at H+5 days will receive:

$$16-12+0.6=4.6 \text{ R}$$

If this is reduced by 25 percent, the effective dose=3.45 R
Permanent personnel will receive:
For first 15 days:

$$16-9+0.6=7.6 \text{ R}$$

Effective 15 day dose=(0.75) (7.6) =5.7 R
For 15 days to 1 year:

$$9-4.5=4.5 \text{ R}$$

Effective dose=(0.5) (4.5) =2.25 R
Total effective dose to end of 1 year=7.95 R
Infinity dose for permanent personnel:

$$7.95+4.5=12.45 \text{ R}$$

REPORT ON EXPERIMENTAL FILM BADGE STUDY DURING OPERATION REDWING, OCTOBER 1, 1956

During Operation Redwing the Public Health Service group had planned, on an experimental basis, to utilize film badges on the off-site atolls of Utirik, Ujelang, and Wotho as a method of securing a figure for total radiation dosage on these islands. Arrangements were made for the procurement, transportation, and processing of film badges with task group 7.1 radsafe personnel and task group 7.4 nuclear research officer, Lt. W. J. Jameson.

The first group of film badges, enclosed in rigid, transparent plastic containers, were exposed for a period of approximately 50 days. A second group was sent out to the atolls and exposed for a period of approximately 15 days. When these films were developed and read, it was found that the results were much higher (up to 5 to 10 times) than would be expected on the basis of exposures computed from instrument readings taken at the atolls (AN/PDR27F geiger counters were used). On examination of the films, water marks could be clearly seen on most of them. It was theorized that heat or moisture, or both, was the cause of the high readings.

Capt. B. H. Purcell, task group 7.1, arranged to have some special film badges prepared. One lot was prepared by having the film packet dipped in Ceresine wax before sealing in the plastic case (referred to in this report as "film dipped badges"). The second lot was prepared by dipping the entire case in wax after the uncoated film packet was sealed in the pastic case (referred to in this report as "case dipped badges").

Preliminary work done on these badges by exposing them alternately to steam and then placing in a refrigerator indicated that they were more resistant to moisture than the regular badges. It was decided to place approximately 20 of each type on each off-site atoll, bringing in 3 sets from each atoll each week until the reliable life of each type of badge in the field could be determined. (Only half as many film dipped badges were available as the other two types.) Unfortunately, for the purposes of this test, the operation terminated before it could be completed. It is believed, however, that some tentative conclusions can be reached from the results obtained.

Films were collected after approximately 1 and 2 weeks' exposures. The balance of the films were collected after approximately 3 weeks' exposure. Readings taken on the films were compared with calculated doses based on instrument readings taken during the same periods. Tabulations of the results are attached.

It can be seen that the doses received during the first week are too low to give reliable results on the film badges used, while exposures received during the first 2 weeks are just at the borderline of sensitivity. All film badges appeared to be satisfactory after 1 week, but after 2 weeks the regular badges were showing signs of moisture penetration. After 3 weeks, almost all the regular badges, while none of the film-dipped or case-dipped badges, were watermarked.

Estimating the dose to which the films brought in after 3 weeks were exposed is complicated by the fact that Parry Island had a gamma radiation level of 20 to 30 mr/hr at the time the films reached there. Thus, it has been necessary to estimate exposure received at Eniwetok Atoll prior to development. How-

ever, a study of the results on these badges is believed to indicate a trend. Attached are curves showing the distribution of results for each type of film from each atoll and the results for each type of film from the three atolls combined.

Considering this latter curve, if one considers results within 50 percent of a "true" (in this case, calculated) dose to be satisfactory, it can be seen that 68 percent of the film-dipped badges and 60 percent of the case-dipped badges fall within this range, while only 19 percent of the regular badges meet this criterion. This is admittedly a limited sample, but the results are believed to warrant the following conclusions and recommendations:

1. Climatic conditions at the Pacific Proving Grounds have an adverse effect on ordinary film badges to the extent that they cannot be relied upon to give satisfactory results;

2. If possible, a study should be made to determine the reliable life of wax-coated film badges and possibly other types of dosimeters) under climatic conditions similar to those at Pacific Proving Grounds prior to the next test series. If this is not possible, such a study should be conducted at Pacific Proving Grounds during the next series.

3. For area monitoring of this type, a more sensitive film should be included in the film packet.

A BRIEF REVIEW OF THE PUBLIC HEALTH SERVICE RADIATION SURVEILLANCE NETWORK OPERATED BY THE PUBLIC HEALTH SERVICE UNDER AN AGREEMENT WITH THE DIVISION OF BIOLOGY AND MEDICINE, ATOMIC ENERGY COMMISSION, MAY 22, 1957

For the principal purpose of providing immediately useful environmental radiological health data, the Public Health Service, by an agreement with the Division of Biology and Medicine, AEC, dated April 15, 1956, established a nationwide radiation surveillance network, with a central laboratory service located in Washington, D. C.

Originally established to encompass the period of Operation Redwing conducted by the United States at the Pacific Proving Ground in 1956, the network stations commenced operation in April 1956 and ceased intensive operation on September 28, 1956. Sampling data were received from Hawaii, Alaska, and 28 States. The gratifying cooperation of the State and Territorial departments of health made possible the staffing and operation of 29 field stations on a cooperative basis.

During the period of September 28, 1956, to May 1, 1957, the Public Health Service encouraged and assisted in the continued operation of the field sampling stations. As a result, between 3 and 8 of the stations continued to submit samples, which were processed in the central laboratory.

An extension of the PHS-AEC agreement, signed on April 18, 1957, provides for resumption of intensive operations during the period of Operation Plumbbob conducted by the United States at the Nevada test site, commencing in May and continuing until November 1957. The number of field sampling stations has been increased to 38, as shown on the accompanying list. Thirty-six of these are operated by State, Territorial, and local health agencies, with the remaining two operated by the Public Health Service.

SAMPLING OPERATIONS

Sampling is performed on a 24 hour-per-day, 7 day-per-week basis wherever possible. Of the approximately 15,000 samples taken in 1956, 9 percent of the air samples were invalid because of equipment failures, and 10 reports failed to reach the laboratory.

Sampling operations at each station include (1) the daily radioassay of beta-emitting particulates with relatively long half lives, collected on a filter from approximately 2,000 cubic meters of air, (2) 2 (or more) daily determinations of external gamma radiation levels with a portable survey meter, (3) collection of radioactive fallout by means of the system developed by NYOO of the AEC, and (4) preparation of preliminary reports from which public information might be made available by State and Territorial departments of health.

During 1957 operations, precipitation samples are also being collected.

CENTRAL LABORATORY SERVICES

The radiological health program, Bureau of State Services, of the Public Health Service, maintains the field stations and provides accurate laboratory confirmation of preliminary field measurements.

Through a closely knit communications network, the radiological health program, PHS, and the Division of Biology and Medicine, AEC, cooperate to provide technical guidance to the State and Territorial health departments in the interpretation of day-to-day results and in replying to public inquiries.

PUBLIC INFORMATION AND CLASSIFICATION

No security classification is imposed on the nature of operations or findings of the network. Because of the approximate values derived at the field sampling stations, it has been requested that only the State and Territorial commissioners of health and the Washington headquarters staff be responsible for replying to public inquiry. No attempt was made to relate the network findings back to specific test operations at the Pacific Proving Ground; instead, interpretation of results has been confined simply to reporting the factual data. This apparently satisfied the numerous newspaper inquiries directed to the State and Territorial commissioners of health.

As far as can be determined, the network operations and the immediate availability of its data help explain, to those of the public who inquire, the dis-

semination of radioactive material from nuclear test areas outside of the continental United States, and the levels of activity which might occur in populated areas in the United States as a result. At many of the field sampling sites, there has been almost daily contact between the State health departments and the newspaper services.

PRELIMINARY RESULTS

During the entire 1956–57 sampling period, external gamma background radiation measurements have remained practically constant at all sampling stations. Depending upon the locality, the background varies from 0.01 to 0.035 milliroentgens per hour and, in general, is typical of that locality.

The beta activity of the particulates in air, having gross radioactive half lives longer than several days, showed minimum average concentrations varying from 0.5 to 1.0 uuc/M^3 at the time of measurement (3 to 5 days after collection). An exception was Alaska, where minimum concentrations were about one-fifth or one-tenth those in the United States and Hawaii.

Before, during, and well after the period announced as encompassing Operation Redwing conducted by the United States at the Pacific Proving Ground in 1956, maximums of air concentrations were noted at all sampling stations, each lasting from several days to more than a week. The highest value, 25.7 micromicrocuries per cubic meter of air, was measured in Honolulu, with equally high values being observed in Austin, Tex., Indianapolis, Ind., Springfield, Ill., and Gastonia, N. C. The latter 4 occurred about 55 days after the announced termination of the United States 1956 tests at the Pacific Proving Ground, and it is difficult to associate these maximums with our tests, because of the long time interval.

Table 1 and figure 1, accompanying this report, illustrate the shift to higher air radioactivity levels at areas east and west of the Mississippi River, at Honolulu, and in Alaska, with the passage of time. The most significant shift to higher air activities occurred after September 1, 1956, at least 30 days after the announced termination of our test operations.

It has been possible to analyze a number of the samples find the approximate date of formation. It should be realized that this method indicates, within limits, the formative age of the more recent fission products in each sample, and is not intended to assess more than the short-term significance of the gross beta radioactivity. Figure 2 illustrates the results of this procedure, and strikingly shows that the major portion of the intermediate half-lived fission products which were samples in the United States could not have resulted from announced test series conducted by the United States. During the 1957 operation all samples will be dated.

Since January 1957, and continuing until the present time, air activity levels measured in the United States have been substantially higher at all locations than for comparable periods in previous years by a factor of about 5 to 10. The radiation samples, when dated, show approximate formative ages coinciding to a degree with publicly announced foreign nuclear tests. The effect is most noticeable in precipitation sample, as described in The Distribution of Radioactivity From Rain, by Dr. Lloyd R. Setter and Dr. Conrad P. Straub (presented for publication proceedings, American Geophysical Union Meeting, Washington, D. C., April 29 to May 1, 1957).

The National Committee on Radiation Protection, in NBS Handbook 52, has suggested 10^{-9} uc/ml (1,000 uuc/M^3) as the provisional level of permissible concentrations of unkown mixtures of beta-emitting radioisotopes in air. When it is reduced to 10 percent of that value as suggested for large population groups, namely, 100 uuc/M^3, we realize that the measured levels of beta radioactivity in air, while generally below the recommended value, are more often approaching this level as time goes on.

The Distribution of Radioactivity From Rain [1]

Lloyd R. Setter and Conrad P. Straub [2]

Fallout measurements, largely as precipitation, have been made on a continuous basis at Cincinnati, Ohio, since March 1953. The studies of 1953 [3] and 1954 [4] were implemented in October 1953 by weekly or daily tests of the atmospheric particulate activity and by the operation of an experimental cistern near the site of the rain collector. Correlation is now possible between air particle concentration and rainout (washout by precipitation) and the distribution of activity between the separated solids and the supernatant liquid in the cistern liquid can be determined. This report includes data relating to activity levels in air particulates, rainfall, and certain Ohio rivers.

METHODS

The methods of sample collection have been described.[4] The precipitation values reported in figures 1 and 2 are the means of values reported for six stations and were obtained from United States Weather Bureau climatological data. To compensate for differences in hours of collection some adjustment in these values was made.

Rainfall was collected in a pail-type sampler, processed to dryness, the gross beta-gamma activity was measured, and the results reported on an area basis.

e. August 27, 1956	1.0

Air particulate activity from January 1, 1955, to August 1956, was determined from swatch subsamples representing roughly 80 cubic meters of air filtered through glass-fiber filters over a 24-hour period, from the Lincoln Park area, Cincinnati.[5] Since August 1, 1956, the air activity reported was obtained by filtering 20 to 30 cubic meters of air through a membrane (cellulose acetate) filter. With the exception of weekend samples collections were made on a daily basis. Sampling was continuous and was interrupted only during the period required to change the filters. After collection, the membrane filter samples were placed in aluminum dishes, saturated with 95 percent alcohol, ignited, flash flamed with a Meeker burner, and counted for two 8-minute periods in an internal proportional counter. To permit decay of short-lived naturally occurring alpha activity[6] counting was delayed for 48 hours.

RESULTS

Precipitation, air particulate, and fallout activity

The precipitation in inches, air particulate activity in micromicrocuries per cubic meter ($\mu\mu c/m^3$), and the fallout activity in millimicrocuries ($m\mu c$) per liter results have been summarized in figures 1 (1955 data) and 2 (1956 data). From decay studies on rain samples it was also possible to determine the age of the samples. This age, shown with the air activity in figures 1 and 2, was obtained by calculating or estimating the slope of the decay rate. For time intervals between such decay curves, the decay rate of later date was used to correct samples collected during the interval indicated.

In general, the results show that increased air activity results in increased activity in the fallout samples collected. This is particularly true for the samples collected in the spring of 1955 during and following continental weapons tests and to a lesser extent for samples collected following foreign weapons tests activities during fall 1955 or Pacific and foreign tests in 1956.

---

[5] Tabor, Elbert C. Protein Content of Air—Final Report of Research for the Chemical Corps Biological Warfare Research Laboratories on Contracts Nos. CD-3-3207 and CD-4-4432, USPHS 1956.

[6] Setter, L. R., G. R. Hagee, and C. P. Straub. The Analysis of Radioactivity in Surface Waters: Practical Laboratory Methods. Submitted for publication in the Am. Soc. for Testing Materials, Bull. 1957.

Considering particulate activity in air from stations in the Midwest (Cincinnati, Louisville, St. Louis, Chicago, Minneapolis, and Detroit) the average background level of approxmately 0.05 $\mu\mu c/M^3$ in the fall of 1953 has increased to an arithmetic average level of 0.6 $\mu\mu c/M^3$ in 1954, 1.55 $\mu\mu c/M^3$ in 1955, and 2.26 $\mu\mu c/M^3$ in 1956. During continental tests in 1955, the activity in Cincinnati air (fig. 1) fluctuated from a high of 10 $\mu\mu c/M^3$ of rapidly decaying radioactivity to a low of 0.08 $\mu\mu c/M^3$ of longer lived radioactivity. Less fluctuation in radioactivity levels (8.9 to 0.58 $\mu\mu c/M^3$) was observed during the Pacific and foreign tests of 1956. Presumably this was due to greater diffusion and decay of radioactivity from a more distant source. However, a higher sustaining level of air radioactivity was noted for the entire year.

As shown in figure 1, 15 rain collections made between March 15 and June 25, 1955, showed activity levels above 30 $m\mu c/M^2$, with the level in 7 of these varying from 141 to 1370 $m\mu c/M^2$. From the decay curves indicated, most of this activity was short lived. Relatively little radioactivity was observed in samples collected during the first 2 and last 6 months of 1955, but the activity collected was of longer half life.

A few peaks of high activity were noted (see fig. 2) during July and September 1956, but fallout levels in excess of 10 $m\mu c/M^2$ were common throughout the year. From the decay curves shown it will be seen that most of the activity collected in 1956 was longer lived than that collected during 1955.

Residual fallout

A somewhat better appraisal of the amount of long-lived radioactive fallout may be obtained by considering the cumulative residual deposition. At Cincinnati, and presumably at all nonarid areas several hundred miles removed from the weapons-test site,[7] increased fallout appears to be associated with periods of rainfall and snowfall.

The fallout, identified quite precisely as to age and rate of decay for the more radioactive samples and less accurately for the low-level radioactive samples, has been decayed to the first of each succeeding month. The cummulative residual activity in millimicrocuries per square meter ($m\mu c/M^2$) of earth's surface, assuming no loss, is plotted as shown in figure 3 for each of the 4 years of record from April 1953 to July 1, 1957. In each year there is a peak of activity during or immediately following test operations. High peaks of 1054 $m\mu c/M^2$ on June 1, 1953, and 970 $m\mu c/M^2$ on June 1, 1955, are shown for the 2 years of continental tests (1953 and 1955), whereas longer lived peaks of 110 and 390 $m\mu c/M^2$ were observed on July 1, 1954 and October 1, 1956, respectively. Fallout during the latter periods was from Pacific and foreign test operations. If a 6-month delay is assumed for observed fallout (that is correcting to the following July 1 after a year of accumulation), the residual activity for each year is as follows:

Year of deposition:	*Residual fallout on July 1 following year of deposition* $m\mu c/M^2$
1953	35
1954	35
1955	90
1956	110
Total 1953–566	270

A steeper decay slope is noted on July 1, 1957, for the 1956 fallout, so that the 110 $m\mu c/M^2$ probably contains about as much long-lived activity as does the 1955 fallout. Nevertheless the table clearly shows approximately a threefold increase in fallout for 1955 and 1956 in comparison to 1953 and 1954.

Assuming that the residual fallout as of July 1, of the succeeding year has an average age of 1 year, one may estimate the strontium-yttrium activity which was deposited. According to Hunter and Ballou[8] the combined activity of Sr^{90}–Y^{90} 1 year after formation is 3.9 percent of the residual or 10.5 $m\mu c/M^2$ deposited over the 4 years. This amount, uniformly mixed with 30 in./yr x 4 yr.

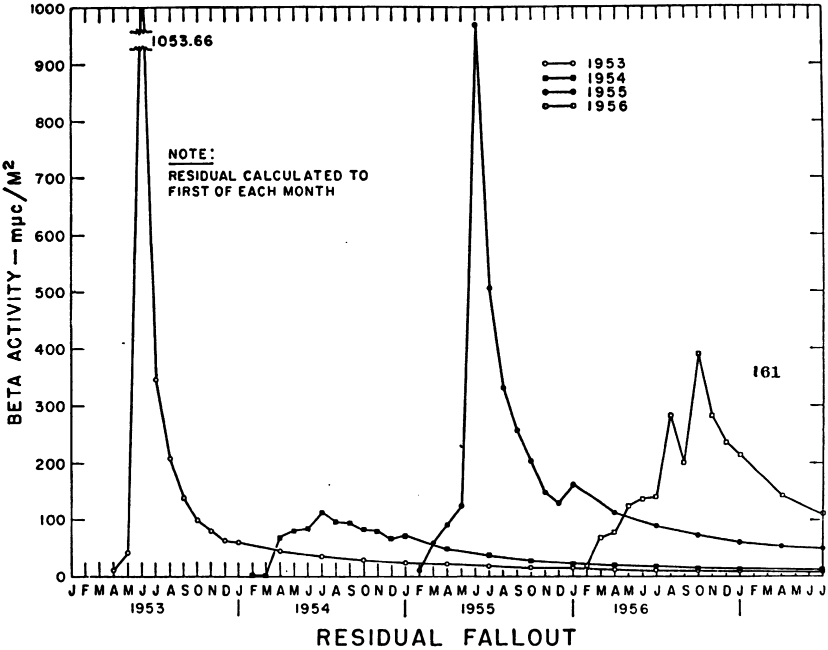
[8] Hunter, H. F., and N. E. Ballou. Fission-Product Decay Rates. Nucleonics, 9, 5, C–2 (November 1951).

FIGURE 3



or 120 inches of rain over 4 years gives a Sr^{90}-Y^{90} concentration level of 3.46 $\mu\mu c/L$ as compared to the maximum permissible level of this parent-daughter combination of 800 $\mu\mu c/L$.[9]

Distribution of fallout in cistern water

Early in 1954, an experimental cistern, consisting of a hopper-bottomed tank of $2.62M^3$ capacity, was installed to collect precipitation from a portion of the roof of an adjacent building. The cistern was in operation from February 10, 1954, to March 7, 1956, and from July 5 to September 25, 1956. During this period, settled cistern water was withdrawn and tested and on 15 occasions the settled sludge was removed and tested. The more significant data from cistern operation are presented in table 1. The total activity found in the cistern water, sludge, and sludge supernatant are indicated in column 7: Sludge supernatant consisted of a known quantity of cistern water (up to 50 liters) required to wash down the cistern sides and bottom. The washed sludge was settled for 10 to 15 minutes and the supernatant removed by decantation. This supernatant was sampled and tested for dissolved and suspended activity in the same manner that the citern water itself was tested. The sludge and supernatant solids contained in the roof drainage amounted to an average of 30 p. p. m. of dry solids (ranging from 9 to 71 p. p. m.) of which about 30 percent were volatile.

[1] All measurements in a series extrapolated for decay to this date.

[2] Obtained from activity (total or dissolved) ÷ total rainfall.

During the 16-month period of cistern operation, the rain collected contained a total of 50.4 μc of beta activity (col. 8) from bomb debris estimated to be 10 to 300 days old. Of this total, 36.72 μc or 73 percent was recovered from the cistern. The remaining 27 percent represents activity fixed to the asphalt roof shingles, and errors in measurement. It is interesting to note that estimations based on the activity found on washed shingle stone separated from the cistern sludge accounted for much more than the 27 percent unaccounted-for activity. However, longer contact was possible in the case of the shingle stone contained in the sludge in contrast to the contact time during roof runoff.

The soluble activity in the cistern water varied from 14 to 55 percent or amounted to 48 percent (weighted average). There seems to be no clear-cut relationship between the percentage of dissolved activity and the age of bomb debris. This is contrary to the observation made in 1953 [3] that the percentage of solubility in the rain was less with shorter lived radioactivity. Other factors, such as nonradioactive air pollutants, the time radioactive particles were exposed to moisture, the size and chemical structure of radioactive particles, and, possibly, the inflow of upper atmosphere contaminants to lower levels in the rainout zone, play a role in forming the soluble fraction. The concentration of dissolved activity in cistern water varied from 7 to 4,160 or an average of 322 μμc/L. Lower values (less than 76 μμc/L) were observed during periods when the bulk of the activity was estimated to be older than 100 days, whereas, for activity 7 to 98 days in age, the dissolved activity was 157 μμc/L or more.

The percentage of activity associated with the suspended solids ranged from 1 to 77 percent, with an average value of about 25 percent.

In summary, the cistern study reveals that slightly more than one-half of the activity found in the cistern water was soluble and that up to a third of the activity would be associated with the suspended solids. Over two-thirds of the insoluble activity settles as a sludge (1.5 kg. dry weight) having an activity of 10 μc/kg. (dry weight). Septicity resulted in further solution of activity, but diffusion into the supernatant was minimal if the sludge was undisturbed.

The distribution of fallout in surface waters

Nine grab and seven composite (7- to 10-day) samples from 13 stations on the Ohio River from Pittsburgh, Pa., to Louisville, Ky., were collected between December 27, 1955, to April 20, 1956, in a cooperative study with the Ohio River Valley Water Sanitation Commission. The maximum beta activity found was 100 μμc/L as compared to an arithmetic average value of 27.5 μμc/L of which 15 μμc/L was in solution.

Additional samples were collected on the tributaries of the Ohio River and tested. Through the courtesy of Mr. F. H. Waring, chief sanitary engineer. division of sanitary engineering, Ohio State Board of Health, some of these results are included in table 2 and figure 4. The samples were collected from the Little Miami, the Great Miami, and Scioto Rivers. Included in the table are maximum and average activity levels of the surface waters as well as Cincinnati rainout results for collections made between river samplings.

TABLE 2.—*The radioactivity of Ohio surface water, 1956, as compared to rainout*

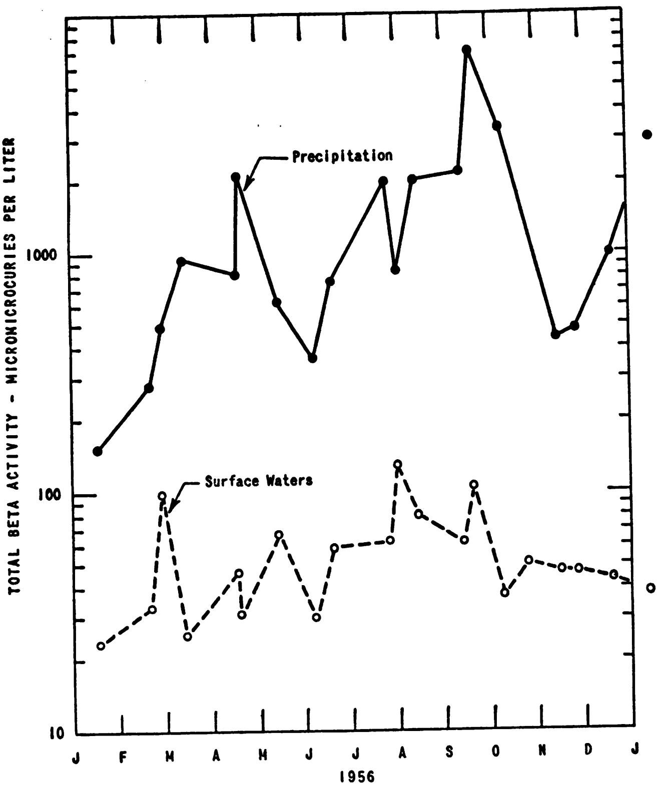
[1] Ohio State Board of Health data on:
A—Little Miami River at Newtown and 5 stations on Great Miami River from river mile 24.8 to 96.6.
B—Four stations on Scioto River from river mile 15 to 140.

[2] Weighted average activity of rain at Cincinnati collected between dates of stream sampling.

FIGURE 4



A COMPARISON OF CINCINNATI FALLOUT IN RAIN WITH THE ACTIVITY OF OHIO STREAM WATER

The results show a maximum dissolved activity level of less than 90 $\mu\mu c$/L compared to a maximum total (suspended and dissolved) activity of 217 $\mu\mu c$/L for the year. The average dissolved activity appears to represent about one-half of the total activity indicated for a given date of sampling. The average total activity for each sampling date fluctuated from 25 to 130 $\mu\mu c$/L, depending to some degree on the activity of the more recent rains. The yearly geometric average values for the surface streams are 27 $\mu\mu c$/L for dissolved or a total beta activity of 50 $\mu\mu c$/L as compared to 389 and 974 $\mu\mu c$/L respectively, for Cincinnati rain. The average yearly removal by natural agents is, therefore, 93 to 95 percent for dissolved and total activity, respectively. Actually, the removals may be even greater inasmuch as some of these streams are known to receive radioactive materials from industrial, research, and medical facilities.

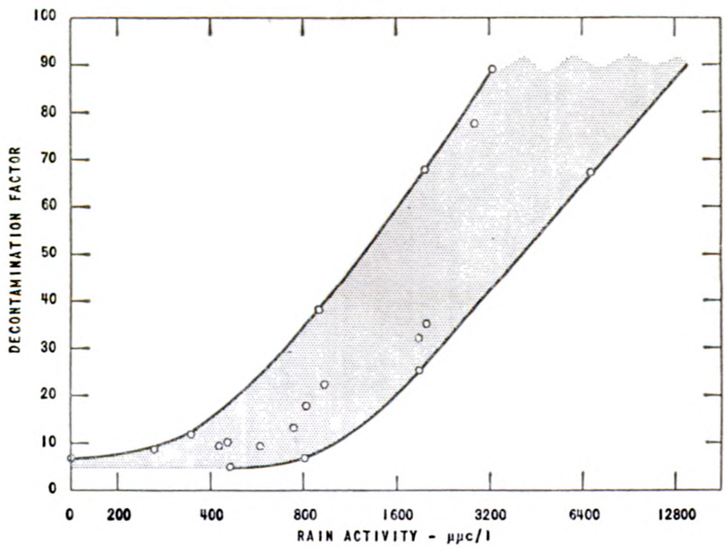
The plotted results (fig. 4) more clearly define the relationship of total rain activity (from Cincinnati fallout) with that found at stream stations up to several hundred miles distance. Obviously, Cincinnati rain and activity measurements can be expected to be at considerable variance to true values at these remote distances. Nevertheless, general trends may be observed and the desirability of establishing more rain monitoring stations as apparent. The rain data indicate a sharp increase (150 to 2,100 $\mu\mu c$/L) during the first of the year, then, following a drop in May and June, a second rise to levels of 2,000 to 7,000 by September. During the last 3 months of the year, the rain activity receded. Lower levels of activity correspond to longer lived bomb debris and high levels correspond to young (short-lived), rapidly decaying, fission products.

The ratio of total rain activity to total surface-water activity was determined for each month, and reported in terms of the decontamination factor (rainout or fallout activity over surface-water activity). These decontamination values were plotted against the rain activity as shown in figure 5. It will be seen that removal by natural agents increases with increased activity of the rain. Comparable in many respects with other pollutants, the plotted values indicate the application of the law of diminishing returns; i. e., high decontamination factors in the order of 65 to 90 (98.5 to 98.9 percent removal) for relatively young bomb debris and decontamination factors of 5 to 10 (80 to 90 percent removal) for lower level, longer lived activity.

For a direct comparison of the distribution of rainout in surface waters of these streams in the general area of Cincinnati, the rainout (corrected for decay to the end of a sampling series) and cistern-water activity of series 11 to 15 (table 1) have been summarized in table 3 with stream tests of appropriate date.

It is seen that subsidence in a cistern results in some purification (21 to 38 percent), adsorption on surfaces such as vegetation, soil and turbidity, percolation, and dilution play important roles in reducing the total activity of rain (91 to 92 percent).

FIGURE 5



THE DECONTAMINATION OF RAIN BY NATURAL AGENCIES

TABLE 3.—*Comparative beta activity of rain, cistern, and stream waters*

[Results in micromicrocuries per liter]

RADSAFE EMERGENCY INSTRUCTIONS FOR POPULATED ISLANDS

1. The commander, JTF–7, has designated a representative for each off-site location outside the PPG. For the populated islands near the PPG, the representative is responsible for the radiological safety of the local population and the members of the task force.

2. The representative of the task force commander is provided guidance as follows:

(*a*) The Marshallese magistrate and irou if on hand and the Marshallese health aid and council on each atoll or island should be assured that every precaution has been taken to prevent exposure of the natives to radiation hazards resulting from fallout.

(*b*) The representative will consult with the local magistrate to insure that a method exists whereby all residents of an atoll may be summoned to a central location and evacuated by air or water transportation if a fallout emergency exists. A fallout emergency will be determined by the commander, JTF–7; however, the local representative will assume that a fallout emergency exists at such time as radiological survey instruments, when held at a position 3 feet above the ground, indicate a rate of 1r./hr.

(*c*) Should evacuation by air be necessary, baggage will be limited to that which each individual can carry or approximately 50 pounds. Whether evacuation is achieved by sea or air, no animals will be evacuated. A tabulation of animals left behind should be made as soon as possible to insure the accuracy of claims against the Government.

(*d*) The local magistrate should be informed that in event of an unforeseen emergency, doctors will be flown from the United States by special airlift to care for local inhabitants who will be evacuated to Kwajalein Atoll and that evacuation plans are in existence to permit the task force to cope with any emergency.

(*e*) Fallout of a dangerous nature can be suspected by the presence of a saltlike precipitate or unexpected mist. Should such an event take place, it should be confirmed by monitoring.

3. The representative will arrange through the local magistrate and native health aid to inform the Marshallese of the basic health measures that they may take to protect themselves from danger in case fallout is suspected or confirmed. These measures are:

(*a*) Remain indoors or under cover to protect themselves from the falling or settling radioactive particles.

(*b*) If particles settle on clothing, dust and shake off clothing.

(*c*) Bathe and keep clean. Particular attention should be given to washing under the arms, the groin, face, and hair.

(*d*) Keep food covered to prevent ingestion of fallout particles.

(*e*) Should the readings exceed 5 r./hr. it is recommended that the natives be advised to stand out in the water (ocean) and immerse themselves as often as practicable or keep themselves under water. This recommendation is based on the fact that water does extremely well in attenuating radiation.

(A report of the Radiological Health Branch, Bureau of State Services, Public Health Service, is inserted at this point in addition to the material submitted.)

RADIOLOGICAL HEALTH BRANCH,
BUREAU OF STATE SERVICES,
PUBLIC HEALTH SERVICE,
October 1952.

SUMMARY OF THE REPORTED RADIATION EXPOSURE IN THE UNITED STATES

I. INTRODUCTION

The program of the Radiological Health Branch, Public Health Service, is directed toward preventing the impairment of human well-being from accidental or unwise exposure to harmful amounts of ionizing radiations and toward improvement of health through judicious use of these radiations. This program can best be accomplished through cooperative efforts of the Radiological Health Branch and the State and local health agencies.

In order to pursue such an objective effectively, knowledge as to the sources of exposure of human beings to ionizing radiation in the United States, the relative importance of these exposures, and the total effect of them on the health of the Nation is a necessity.

This paper summarizes the available unclassified published data on current sources of radiation exposure in the United States and their relative quantitative importance. It is expected that the future will bring nuclear reactors for power purposes into widespread use. The quantities of radioactive materials involved will dwarf the presently produced sources of ionizing radiation. The competence of the health profession to cope with the increased problems arising from these new sources of radiation will be determined by the training and experience of its members in handling present radiological public health problems. Now is the time to prepare to meet the health problems of the nuclear-power industry.

II. SOURCES OF RADIATION EXPOSURE

The existing radiation exposure in the United States (exclusive of natural background radiation) originates from the use of radiation-producing machines and radioactive substances in many fields—broadly covered by the terms "the healing arts," "industrial usage," "commercial usage," and "investigative (research) usage."

The following table lists the sources of radiation exposure in the United States about which the Radiological Health Branch has been able to collect information.

Data currently pertinent to radiological health surveys

Radiation source	Cause of exposure	Where found	Persons exposed
X-ray	Healing arts:		
	Diagnosis (radiography and fluoroscopy) and therapy.	Hospitals, clinics, private practice, dentistry, dermatology, veterinary practice, chiropody, osteopathy.	Doctors, nurses, technicians, dentists, patients, persons holding or positioning patients, X-ray unit repairmen, bystanders and persons in adjoining offices or on floors above or below.
	Mobile and portable chest X-ray units; multiphasic testing units.	Trailer stations, community buildings, fairgrounds, etc.	Same as above with additional community participants, volunteer workers, local health department staff, etc.
	Industry:		
	(1) Radiography (permanent mobile and portable units); inspection of welds, castings, pressure vessels, and parts.	Nonferrous foundries, boiler-shop products, aircraft engines and parts, metal-working machines, steel foundries, gray-iron foundries, tires, V-belts, and inner tubes, propeller blades, electric welding apparatus, bronze babbitt, special industrial machinery, general industrial machinery, models and patterns, railroad cars and street cars, carbon and graphite products, motor vehicle, motor-vehicle parts, vacuum cleaners, motor, generator and motor generators, electric lamps, business machines.	Operators, observers, bystanders, persons in adjoining rooms, repairmen.
	(2) Fluoroscopy:		
	Inspection devices:		
	(a) Manufactured products	(1) Tires, V-belts and inner tubes, carbon and graphite products, vacuum cleaners, rubber industry, electrical equipment for industrial use.	Operator, observers, bystanders, repairmen.
		(2) Food-processing and packing plants	Operator.
	(b) personnel and packages	(1) Prisons, factories, defense plants, police, post office.	Operator, "patient," repairmen.
	(3) High-vacuum electronic tubes	Electronic tube manufacturers and users, testing and operation of the tubes.	Testers, observers, operators, bystanders.
	(4) Theater or projection type TV tubes	Theaters	Operator, repairmen, persons near tube face.
	Commercial usage: (1) Shoefitting	Shoestores	Shoe salesmen, customers, clerks, bystanders, repairmen.
	Research:		
	(1) Variations in electric potentials	Industrial oscillographs	Technicians, experimenters, and repairmen.
	(2) X-ray effects and diffraction studies	Research laboratories, educational institutions.	Do.
	(3) Microscopy-electron microscopes	do	Do.
	Accidents	In all phases	Potentially all users.

Data currently pertinent to radiological health surveys—Continued

Radiation source	Cause of exposure	Where found	Persons exposed
Cathode rays	Sterilization:		
	(1) Food	Food industry	Operator, repairmen.
	(2) Drugs	Drug industry	Do.
AEC distributed radioisotopes (does not include radium).	Transportation of isotopes	AEC to user	Carriers.
	Medical application: Diagnosis and therapy	Hospitals, clinics, private practice, pharmaceutical houses.	Laboratory personnel, doctors, nurses, technicians, patients, persons close to patients, persons handling clothing, bedding, etc., of patients.
	Industrial application (partially research):		
	(1) Radiography (cobalt 60) thickness gages, liquid level gages, density meters.	Automobile companies, oil industry, coating industry, steel companies.	Workmen, operators, bystanders, technicians.
	(2) Movable sources, liquid flow through pipes, location of "go-devil".	Rubber industry, pipeline industry, soap companies, laundry equipment manufacturers, coke industry, metallurgy.	Do.
	(3) Tracers, friction, wear, solid diffusion, detergency, mineral flotation, movement of preservatives, role of catalysts, Fischer-Tropsch synthesis, source of coke sulfur.	Industrial laboratories and test sites	Do.
	Research:		
	(1) Animal and plant physiology	Academic institutions, research groups	Laboratory personnel.
	(2) Bacteriology		Do.
	(3) Chemistry		Do.
	(4) Physics		Do.
	(5) Fundamental medical	U. S. Public Health Service (NIH)	Do.
	Isotope chemistry: (1) Preparations of radioisotopes for special uses.	Industrial laboratories	Do.
Non-AEC distributed radioisotopes (cyclotron produced).	Medical, industrial, research applications	Medical and industrial laboratories, colleges and universities.	Do.
All distributed radioisotopes (does not include radium).	Wastes	Air decontamination, soil contamination, water contamination.	Potentially all users, sewage-works operators, plumbers and persons downstream or downwind from user.
	Accidents	In all phases	Potentially all users.
Fission products	Industrial application	Industry	Few at present. (Field should expand.)
	(1) Activation of phosphors.		
	(2) Static eliminators.		
	(3) Fluorescent light tubes.		
	(4) Instruments containing radiation sources.		
	(5) Sterilization of food and drugs.		

Radium	Transportation of source	All sources are portable	Carriers.
	Medical application:		
	(1) Preparation of radon needles	Hospital, clinics	Laboratory personnel.
	(2) Therapy (radon and radium)	do	Laboratory and medical personnel, patients, persons near patients.
	Industrial application:		
	(1) Radiography	Inspection of welds, castings, pressure vessels.	Operation personnel.
	(2) Static eliminators	Coating industry, textile industry, all paper trades, printing, photographic processing, plastic manufacturing, telephone companies.	Personnel nearby machinery, maintenance and repairmen.
	(3) Activation of phosphors	Sign companies	Workers.
	(4) Luminous compounds	Radium dial industry	Workers, bystanders, users of product, personnel handling storage of products.
	Radium reprocessing	Radium industry	Workers.
	Accidents	In all phases	
Polonium	Industrial applications:		
	(1) Static eliminators	Printing shops	Manufacturers and users.
	(2) Film brushes	Film companies	Do.
	(3) Activation of phosphors	Sign companies	Do.
	(4) Spark plugs	Spark-plug manufacturers	Do.
Thorium	Industrial and research applications	Gas mantle manufacturers, research groups (neutron sources), thorium salt manufacturing and compounding.	Manufacturers (research personnel) and users.
Neutron sources (radium-beryllium)	Research application	Research institutions	Workers, handlers.
Radioactive scrap	Contaminated platinum and gold laboratory scrap and equipment.	Precious metals reclaiming companies	Process operators, sweepers, receiving clerks, stock handlers.
Nuclear reactors	Research, educational, industrial, medical, and military applications.	Educational institutions and industry	Persons working around reactors and handling the products.
	Wastes	Air contamination, soil contamination, water contamination.	Surrounding populace.
	Accidents:		
Raw materials for nuclear reactors	Uranium mining and milling, handling and shipping.	Transportation centers and Colorado Plateau.	Mine and mill workers, transporting workers, processing workers.
Particle accelerators	Industrial, medical, and military research.	Educational institutions	Research personnel.
Atomic weapons	Weapons tests	Air contamination, soil contamination, water contamination, food contamination.	Detectable in all United States.
AEC installations	Plant wastes	Air contamination, soil contamination, water contamination.	Environment surrounding various Atomic Energy Commission sites.

NOTE.—This chart represents a revised version of an earlier chart prepared by the Radiological Health Branch. Information furnished by the New Jersey State Health Department was utilized in the preparation of the revised chart.

III. RADIATION EXPOSURES

A. Background radiation

The human race has always been exposed to some ionizing radiation. It is continually being irradiated by radiation from natural sources in the general environment such as uranium, thorium, actinium, radium, radon, and their decay products, from cosmic radiation, and from cosmic-ray induced radioactive materials (1). The aggregate of these radiation sources is known as the natural background radiation. A person who lives to be 70 years of age is exposed to a total of about 9 roentgens background radiation during his lifetime (2).

B. X-ray in the "healing arts"

There are more than 125,000 X-ray units in the United States being used for diagnosis and therapy. Some 50,000 of these units are used by general practitioners, physician specialists, radiologists, and in hospitals and clinics (3). Approximately 65,000 of the units are used by dentists (4). It is estimated that some 11,000 are being used by doctors of osteopathy and doctors of chiropractic (5).

There are more than 215,000 operating personnel potentially exposed to radiation in the use of these X-ray units in the United States. These include some 3,000 radiologists devoting full time to their specialty, 500 physicians devoting most of their time to radiology, 600 physicians who are second- and third-year residents in radiology, 31,000 general practitioners and physician specialists owning their own equipment (3), 67,000 dentists utilizing X-ray equipment (4), and some 11,000 osteopaths and chiropractors using X-ray equipment (5). In addition, there are some 40,000 X-ray technicians (6) and probably close to 50,000 dental technicians and assistants (7) (8) currently potentially exposed to radiation. This listing undoubtedly omits many nurses, clerks, attendants, technicians, and others also exposed more or less often to radiation.

Many instances of excessive exposure of X-ray personnel in the United States are reported in the literature (9), (10), (11), (12). However, few specific data are available regarding average exposures for such workers. In one 9-month survey (13) of personnel in 4 X-ray departments, it was found that about 0.5 percent of the weekly exposures exceeded 0.3 roentgen. However, 97 percent were less than 0.05 roentgen. In a similar 3-week survey (13) of personnel in doctors' and dentists' offices and X-ray departments, 3 percent of the weekly exposures exceeded 0.3 roentgen with 81.5 percent being less than 0.05 roentgen. Surveys of United States Public Health Service hospitals by the Radiological Health Training Section, Cincinnati, Ohio (14), have revealed exposures ranging from 0 to 0.46 roentgen per 2-week periods for X-ray personnel. It has also been reported (15) that an appreciable fraction of radiologists experience exposures on the average of more than 0.1 roentgen per day and that 20 percent of the personnel operating photofluorographic equipment exceed 0.3 roentgen per week (16). For dental X-ray it has been reported (17) that the operator receives approximately 0.1 roentgen of general body exposure per 8 examinations of the mouth, each of which consists of a series of 103-second exposures. This assumes careful operation of the unit. Dental operators conducting mass dental X-ray surveys can easily receive present-day maximum allowable radiation dosages, even with some rotation of operators. Personnel in the immediate area of such dental X-ray units can receive appreciable percentages of daily and weekly maximum allowable limits (18).

In the United States, about 2,500,000 persons are seen each day by physicians. A large number of these people have some X-ray diagnostic procedure performed upon them by the physicians and, in addition, more than 82,000 of them are referred to radiologists (3).

Radiologists give approximately 25 million X-ray examinations annually (3). The following table summarizes the data relative to radiation exposures resulting from these examinations. These data have been obtained by the Radiological Health Branch from the published literature (2), (3), (15), (17), (19) through (28).

TABLE I.—*X-ray examinations*

Type	Average dosage (roentgens)	Relative distribution of each type	Roentgen dosage for average examination
		Percent	
Radiographic	2.7	51.88	
Photofluorographic	1.0	33.64	11
Fluoroscopic	65.0	14.48	

Probably the largest single contributing source to the total medical radiation exposure in the United States is the mass chest X-ray survey for tuberculosis. An estimate for 1950 as to the number of persons given chest X-rays in such surveys would be about 15 million (29). A portion of the 25 million X-ray examinations given annually to persons seen by physicians is probably included in the 16 million chest X-rays because of inherent overlap of the reporting procedures. Most of the X-rays given in the mass survey are of the photofluorographic type. This type of examination results in about 1.0 roentgen exposure to the chest of the patient (15) (21).

More than 4 million X-ray *treatments* are given annually to the 82,000 persons referred daily to radiologists (3). These treatments are confined as a rule to a very small portion of the patient's body. The average dosage received is of the order of 6,000 to 7,000 roentgens per treatment (30) through (34).

It has been estimated that in 1949 60 million persons (40 percent of the population) in the United States visited their dentists (8). Some 84 million roentgenograms are taken annually for dental X-ray purposes (35). The average exposure to the mouth of the patient is about 5 roentgens per film (36). Total body irradiation is a fraction of this amount.

C. X-ray in industry

Industrial X-ray devices include primarily (*a*) radiographic and fluoroscopic units used for the determination of defects in castings, fabricated structures, and welds, and (*b*) fluoroscopic units used for the detection of foreign material as in packaged foods.

It is estimated that there are at present approximately 800 active industrial *radiographic installations* in the United States (38). The total number of X-ray *units* (both radiographic and fluoroscopic) in use in industry is probably about 2,000 (40).

In a survey of 61 industrial radiographic X-ray units in Ohio (37) it was found that some 400 persons were potentially exposed. Applying this ratio to the 800 active industrial radiographic installations in the United States (assuming 1 unit per installation), it can be estimated that some 5,000 persons are potentially exposed to radiation from industrial radiographic installations in this country. Numbers of personnel exposed in the use of industrial fluoroscopic units are not known.

The hazards of X-radiation in industry are due to the high intensities employed, the frequency of operation (11), and the use of "homemade" or makeshift equipment or equipment originally designed for other purposes. It is not unusual for one radiographic installation to expose a thousand films in 1 day (39). Energy levels for radiographic installations range up to greater than 1,000 kilovolts. The use of makeshift equipment is especially hazardous in industrial fluoroscopy (39). However, this does not mean to imply, ipso facto, that all other fluoroscopy units are absolutely safe regardless of the manner of their operation.

Exposure levels for personnel in industry depend upon the installation. Most installations were designed and the personnel assignments planned so as to limit personnel exposures to the levels recommended in the National Bureau of Standards Handbook current at the time the equipment was built. However, the continual revision downward of maximum permissible exposure limits (currently 0.3 roentgen per week) calls for a reevaluation, by survey, of the older installations.

In the use of fluoroscopy for the scanning of personnel, such as at prisons, exposures of 0.045 to 0.09 roentgens per inspection may be received by the "patient." In addition, the unit operator may receive about 0.1 roentgen to the head and shoulders for each 50 persons inspected (11).

It has been reported (45) that during the manufacture, testing, and operation of high-voltage electronic tubes measurable amounts of potentially harmful X-rays were produced. In one industrial situation studied the exposure to the operator was found to be as high as 2.5 roentgens per day (45).

Theater- or projection-type television tubes have also been reported as sources of X-radiation.

D. Commercial use of X-ray

In the use of fluoroscopy in shoe-fitting, mean exposures from 7 to 14 roentgens per 20 second exposure (an average setting) have been reported (41 (42 (43). Although exposure is intended for the feet of the customer only, dosages of 0.03 to 0.17 roentgen per 20 second exposure have been reported as being received by the pelvis (44). The number of exposures received by shoe customers is not known. It is estimated that the 30,000 to 40,000 persons (shoe salesmen, clerks, and bystanders) are exposed chronically in the operation of the some 10,000 shoe-fitting fluoroscopes in the United States (42) (43).

E. X-ray in research

With the development of atomic and nuclear physics, high voltage X-ray machines have become familiar features of the average laboratory found at universities and similar institutions.

Few data are available as to the levels of exposure received by personnel in such radiation laboratories. Injuries have probably been held to a minimum by frequent turnover of personnel under university laboratory conditions. However, in such laboratories where cyclotrons, linear accelerators, and positive ion tubes, as well as high voltage X-ray machines, have been used, it is estimated there has been a frequency rate of 1 palpable injury per 20–30 man-years of active employment in radiation work (46).

There are about 1,500 X-ray diffraction units in the United States (40). Radiological Health Branch surveys of these units have recorded intensities of scattered radiation up to 1 roentgen per hour (14). There have been several reports of skin ulcers resulting from accidental overexposures in the use of this type equipment (39).

Many research laboratories today use the electron microscope. There are approximately 500 in use in the United States. Several authors (47) (48) (49) have presented papers on the exposure associated with radiation from these units. Intensities of scattered radiation ranging up to 1.5 roentgens per hour have been reported (47).

F. Radioisotopes (excluding radium)

More than 900 universities, hospitals, and research laboratories in the United States have or are using radioactive isotopes produced by the United States Atomic Energy Commission for medical, biological, industrial, agricultural, and scientific research and medical diagnosis and treatment (50) (53).

In a survey (51) of the available radiobiological research and training facilities throughout the United States and Canada, of 153 institutions covered, more than 1,300 staff members and 800 graduate students were engaged in work with isotopes. In 76 of the institutions, isotopes were being used in patients for research, diagnosis, and therapy. It has been estimated that a total of some 7,500 persons are currently engaged in work utilizing radioisotopes in the United States (52).

Of the users of radioisotopes, on the average, about 1 in 300 exceeds the present day maximum permissible radiation exposure (0.3 roentgen per week) and 50 to 75 percent receive less than 0.05 roentgen per week.

During 1950, an average of 45 curies of radioactive isotopes were distributed per month (52).

1. *Medical.*—Radioisotopes are used medically for diagnosis and therapy. Patients to whom these radioisotopes are internally administered may receive 10 or more roentgens whole body exposure from diagnostic doses and from 75 to 100 roentgens from therapeutic doses (54). Single organs such as the thyroid gland may receive from 10,00 to 300,000 roentgens total tissue dosage (55).

It has been recommended as a public health precaution that "patients who receive large doses of I^{131} or Au^{198} should be hospitalized until the total residual activity in the body is not over 30 millicuries" (56).

Radioisotopes are also used in medical therapy as external sources of radiation. Beta ray applicators are available for the treatment of certain eye conditions. Cobalt 60 sources are available in the form of large shielded concentrated

sources for deep therapy and in the form of small needle sources for intracavitary and interstitial therapy.

2. *Industry.*—Cobalt 60 is being used industrially for radiography. There are currently about 80 sources being used in the United States in such industries as railroads, steel, boiler, automotive, ceramics, pressure vessels, and castings (57). The intensity of radiation from 1 curie of unshielded cobalt 60 at 1 foot distance is 14.4 roentgens per hour (50). The quantities used in industry range from one or two hundred millicuries up to as high perhaps as 1 curie (58).

Thickness gages, using radioisotopes, are becoming more and more popular in industry. There are more than 50 utilizing strontium 90 and some 20 utilizing other radioisotopes presently in use in the United States (60). Surveys have shown that the external radiation to which personnel working around the units are exposed is well below permissible limits (61).

Strontium 90 is also being used as a source of ionizing radiation in luminous paint.

These and other radioisotopes are also being widely used in a variety of industrial research problems.

Wastes: Wastes from the use of radioisotopes in industry, the medical profession, and research laboratories, could cause radiation exposure to persons outside the installations using the radioisotopes. Safe disposition procedures have been well covered in official publications (62) (63). Estimates as to the adequacy of disposition methods presently in practice vary (64) (65).

G. Radium

The radiation from 1 curie of radium, inequilibrium with its decay products, and enclosed in 0.5 mm. of platinum, will produce a gamma ray exposure of about 9 roentgens per hour at a distance of 1 foot (66).

1. *Medical.*—In the medical use of radium, the technician, therapist, patient, and persons near the patient (other patients, nurses, and attendants) are exposed.

Since radium seldom can be applied to the patient remotely with accuracy, radium technicians and therapists often receive relatively large exposures. It has been reported in England that the local exposure to their hands in many cases exceeds 1 roentgen per day (67). Other exposure occurs in the preparation and handling of radon capillaries.

It has been reported that the average daily exposure in a typical teleradium installation in England ranged between 0.13 and 0.25 roentgen (68).

In radium therapy, patients receive radiation dosages comparable to those given in X-ray therapy.

2. *Industry.*—(*a*) Radiography: In 1948, approximately 50 grams of radium were being used for radiography in the United States (69). During World War II, this figure reached 100 grams (69), largely due to the fact that X-ray units were difficult to obtain. At present, much of the radium-radiographic work that was done during the war has been discontinued and X-ray machines and cobalt–60 are being used instead.

Radium sources are commercially available in 25, 50, 100, 200, 300, and 500 milligram units. The 100 and 200 milligram sources are most commonly used (69).

Average exposures received by industrial personnel handling radium are not known.

(*b*) Luminous compounds: Several hundred grams of radium were utilized in the luminous compound industry in the United States during World War II (73). During this period there were several thousand workers engaged in the use of self-luminous paints. After World War II, the number decreased and in 1948 there were only about 300 people engaged in this work in the United States (69).

Although individual workers handle only small quantities of radium daily, the hazards to health from this use of radium are significantly greater because it is not sealed in a container and, therefore, can be ingested or inhaled.

Under present conditions, it is recommended that no worker exceed a maximum permissible amount of 0.1 microgram radium fixed in the body (70). Under the best working conditions existing in 1943 in the radium dial painting industry, 15 percent of the workers accumulated more than the maximum permissible amount (71). It has been reported (72) recently that a survey in a military-aircraft-instrument shop, which followed the safety regulations of the National Bureau of Standards, found a degree of radium contamination greatly in excess of the maximum permitted.

It is generally accepted that the maximum allowable level for radon in the air is 10 micromicrocuries per liter (46). It has been reported that when workroom ventilation requirements are met, the radon concentration in the workroom air will not exceed 30 percent of the maximum permissible limit (71). However, ventilation requirements are not always met, especially in storage and packing rooms and offices.

The normal gamma radiation exposure received by dial painting workers appears to be about 0.02 roentgen per day (46).

Exposures may also occur in the use of the finished product to which a luminous compound has been added. A watch may have approximately 1 microgram of radium on it. Some clocks and aircraft instruments may contain from 10 to 100 micrograms of radium (74). It has been reported (74) in surveys in airplanes that the level of exposure at the instrument panel was 0.01 roentgen per hour and from 0.0002 to 0.001 roentgen per hour at the pilot's body position.

(*c*) Reprocessing and preparation of radium and radon sources: Radium preparations that have become obsolete in either design, or use, or the seal of which has broken or worn thin, should be reprocessed. This work involves hazards similar to those encountered in the subdivision of radium into capsules for medical or industrial use. The work is performed by relatively few companies. However, the work has not been governed by general regulations of the type applied to the luminous compound industry. A radon concentration of 2,200 micromicrocuries has been quoted as average in the general laboratory of one of the most reputable companies (46).

The operation of radon plants, commercially or in hospitals, can be very hazardous since the worker is exposed not only to radon but also to beta and gamma radiations of the radium and its decay products.

(*d*) Static eliminators: Static eliminators are widely used in textile and paper trades, in printing and photographic processing industries, and by telephone and telegraph companies.

One type, the ionotron, consists of a bar containing a strip of metal impregnated with radium. A thin layer of gold and nickel are plated over the radium-metal strip to protect the radium and act as a seal.

The main hazards from the ionotron are exposure to beta and gamma radiation (alpha constitutes little external hazard) and radon gas.

Actual exposures of 0.003 to 0.005 roentgen per hour for pressmen and 0.5 to 1.0 roentgen per hour for maintenance personnel have been reported in a survey of a printing plant (75). Fortunately the latter duties required only about 15 minutes per day of such exposure.

In other surveys, levels up to 0.085 roentgen per hour have been reported in the working area near such units (69).

The radon hazard from ionotrons is small, if they are given proper care. However, if the seal is broken, a radon hazard may result. Several surveys have pointed out that improper storage and handling of static eliminators is common (76).

A second type of static eliminator, the alphatron, contains polonium as the radioactive source. These units constitute little external radiation hazard since the alpha particles from polonium travel only a short distance in air. The hazards associated with their use result primarily from ingestion or inhalation of polonium liberated through breaking of the gold seal and flaking (77).

Polonium will volatilize at lower temperatures than radium and careful consideration must be given this point in certain specialized applications (77).

Static eliminators are also used with analytical balances and microtomes.

Polonium bars are also mounted on brushes for use as a static charge eliminator for phonograph records and photographic films.

Lost radium: Numerous instances of radium being lost have been reported in the newspapers. Taft (78) has reported on 107 losses with 59 complete recoveries, 11 partial recoveries, 36 total losses, and 1 unknown result. There is danger of unsuspected radiation exposure in all such instances.

Shipping of radioactive materials: Exposures can occur during the handling and shipping of radioactive materials. Interstate Commerce Commission and Post Office Department regulations governing the shipment of radioactive materials by domestic ground and water transport and the interim regulations for shipments by air attempt to accomplish three objectives:

(1) protection of people,
(2) protection of film,
(3) avoidance of excessive shielding weight (excessive carrying charges).

It has been reported that the maximum exposure which an airplane crew member or passenger would receive under the regulations would be 0.012 roentgens per hour. Maximum exposure for pilots (flying 85 hours per month) would then be 1.02 roentgens per month (74).

H. Nuclear reactors

A "water boiler" (79) type nuclear reactor is being built at the North Carolina State College. Data on this reactor can serve as a tentative guide in establishing the importance of such installations with regard to the radiation levels in the United States.

The North Carolina reactor is to operate at a maximum of 10 kw. Heavy shielding will limit the exposure, resulting from a maximum of some 105 curies of activity present, to a safe level.

The heat generated during operations will be removed by circulating water through sets of cooling coils inside the reactor cylinder. This water, from the Raleigh city system, will be fed into the reactor after passage through automatic pressure reducing-regulating valves; at 10 kw. power level a total of 3 gallons per minute will be required.

The intense neutron bombardment received by the coolant in passing through the reactor will induce radioactiivty in it (principally in the dissolved and suspended solids). The resultant activity will be near 1,000 disintegrations per second per cubic centimeter initially. Assuming no shielding and no internal absorption of radiation by the water, 10 gallons of freshly irradiated water would produce a radation dosage rate of approximately 0.08 rotentgen per 8 hours a distance of 5 feet. After 1 hour, the dosage rate would drop to about 0.0008 roentgen per 8 hours at a distance of 5 feet. Tanks for collecting and retaining this waste water for 10 hours are provided.

The reactor in operation produces a small volume of gaseous fission products, resulting from the fission of uranium into elements of gaseous nature, and larger volumes of other gases resulting from the decomposition of the water molecules in the fuel solution into hydrogen and oxygen. The activity of the fission product bases will be considerable, amounting initially to about 7,000 curies per kilowatt-minute. However, after 4 hours, the 7,000 curies will have decayed to 0.15 curies. The activity of the decomposition gases will be negligible. At 5 kilowatt operating level, the total volume of gases produced will be 40 liters per hour. Solid as well as other liquid and gaseous wastes will result if laboratory or experimental programs are conducted in conjunction with operation of the reactor.

It has been reported that at least five major universities have expressed interest in following the steps of North Carolina State College by building research reactors outside of Atomic Energy Commission sites (81). Undoubtedly, other reactors will soon be built at other colleges and universities and in industry.

A second type reactor is being built by North American Aviation, Inc., in California (80). It too should serve as a guide in establishing the importance of such installations in the total radiation exposure in the United States. The reactor is to be of the enriched-uranium, graphite-moderated, type and will be used for research. It will be operated at a designed capacity of 160 kilowatts and will be shielded by 6 inches of steel and about 3 feet of "heavy" concrete (total weight 450 tons). Data as to the wastes to be produced by this reactor and resulting radiation exposures have not been released.

I. Particle accelerators

In 1941, there were only some 16 cyclotron laboratories in the United States (12). It was reported that due to the tremendous cost of particle accelerator units (namely cyclotrons, synchrotrons, Van de Graaff generators, and betatrons), their number was not apt to grow to more than a few dozen (82). However, the impetus to nuclear research created by the atomic energy program has caused their number to increase to over 100.

For example, 20 machines came into operation in 1950 and 21 in 1951 under auspices of the Atomic Energy Commission (83). One company reported, in a recent advertisement, that it had built 15 Van de Graaff Electrostatic Accelerators at research installations in the United States (84).

Exact determination of the type and intensity of radiation encountered around particle accelerators is often difficult or impossible because of the mixture of radiations present (85). Beta radiation originates from the various accelerators but the possibility of direct exposure is slight (85). Neutrons probably constitute one of the main hazards as they are produced in profusion in the operation of cyclotrons and synchrotrons (82).

Impaired vision of several nuclear physicists as a result of work with cyclotrons was reported recently (86). The general injury rate for laboratory radiation workers was discussed under the portion of this paper covering "X-Ray in Research."

J. AEC activities

Activities of the Atomic Energy Commission in the fields of fissionable material production and weapons testing contribute to the level of radiation to which special groups and the general public are subjected. Specific items are:

1. *Uranium mining and milling.*—The uranium mining and milling activities in this country are predominantly restricted to the region of the Colorado Plateau. Some 2,000 miners and millers are engaged in this work (87). It has been reported that the mining and processing of the ores and metals yield dusts and fumes which are sources of radioactive air pollutants (88). The United States Public Health Service and several State agencies are active in studies of the specific hazards in this industry (89). They have reported finding radon exposures above the maximum permissible limit in several of the mines. In these instances, control measures are being applied as rapidly as possible.

2. *Operation of nuclear reactors.*—Operation of nuclear reactors within the Atomic Energy Commission contribute to the magnitude of the radiation exposure in the United States. It has been reported that the use of air for cooling purposes in nuclear reactors is a source of radioactive air pollutants (88). The use of water for cooling purposes at Hanford contributes radioactivity to the Columbia River.

3. *Other AEC plant wastes.*—Chemical dissolving and separation processes and the operation of "hot" laboratory hoods plus the incineration of contaminated solid materials (such as experimental animals) are all sources of radioactive air pollutants (88).

Since the operations producing these radioactive air pollutants are widespread, the potential hazards are by no means always confined to those directly employed in such activities. The discharge of radioactive gases, dusts, and other radioactive pollutants outside the immediate area of operation may greatly increase the radius of the possible health hazards (90).

The chemical dissolving and separation processes also contribute liquid wastes. It has been reported that the Oak Ridge installation of the AEC discharges up to 5 curies per day of liquid wastes (91).

4. *Weapons tests.*—In 1951 12 bombs were dentonated at the AEC Proving Ground in Nevada.

The fission product activity 1 hour after the dentonation of a nominal atomic bomb is in order of 10^9 curies. One week later, there are still about 10^7 curies remaining (92). Fortunately the majority of this activity probably remains in the upper atmosphere. However, some of it is distributed over most all of the United States. For example:

(*a*) Radioactive snow has been reported falling over wide portions of the United States following these tests (93).

(*b*) The background count in many radiation laboratories increases by a factor of 5 to 10 during these periods, necessitating in many instances the curtailment or complete stopping of counting activities.

(*c*) Film manufacturing companies must take precautions to prevent fogging of their film during these tests (94). In the 11th semiannual report of the AEC, it was stated that the photographic industry must specially treat water used during these periods due to contamination from fallout (83).

K. Other factors affecting exposure levels

1. *Availability of radioactive materials.*—Under the law, the Atomic Energy Commission carefully controls the distribution of radioactive materials produced in its operations. However, naturally radioactive materials are not subject to similar regulations. As a result, certain products containing small quantities of naturally radioactive materials may be purchased on the open market. For example, brushes for use as static charge eliminators (polonium), and instruments with luminous dials (radium). The high cost of large quantities of radium (such as are used for industrial radiography and medical therapy) and the care exercised by the radium companies in their distribution tend to eliminate them from the "open market" classification.

2. *Fission products.*—Only about 4 curies of fission products had been distributed by the Atomic Energy Commission through 1950; the rate of distri-

bution is expected to increase considerably within the next few years. Suggested uses for fission products include:

(*a*) Activation of phosphors.
(*b*) Static eliminators.
(*c*) Fluorescent light tubes.
(*d*) Instruments containing radiation sources.
(*e*) Industrial radiography.
(*f*) Cold sterilization of food and drugs.

L. Accidents

Accidents appear to be an implicit complication of all activities involving man. There is no reason to believe that his activities in the radiation field will differ in this respect. In fact, numerous instances of radiation injury have been recorded in the literature (39) (86) (97) (98) (99). In addition, based on private conversations, it is believed that only a small fraction of the accidents which do occur are ever recorded in the literature.

Any radiation exposure from accidents would be in addition to the exposures listed elsewhere in this article. Obviously, the potential amount of exposure and the probable severity of injury incurred in an accident would vary with the amount of radiation involved.

IV. COMMENTARY

A summary of the published literature available to the Radiological Health Branch and pertaining to the sources and levels of radiation exposure in the United States has been presented.

Definite conclusions concerning the relative public-health importance of the several categories of radiation sources in the United States should not be drawn from the data presented since the amount of the published literature in each field largely determined the data available.

The public-health importance of individual sources will vary for different localities. Furthermore, this relationship is constantly changing. For example, many radiation-minded health people feel that, in the future, use of nuclear reactors in research, medicine, and industry will be the biggest public-health problem.

This paper is intended to serve as a guide to the State and local health officer in seeking out, evaluating, and controlling the radiation affecting the public health in his area. If it is of assistance in initiating a radiological public-health program at the local level, it will have served its purpose.

The committee will stand in recess.

(Whereupon, at 12:30 p. m., the committee recessed, to reconvene at 2 p. m., of the same day.)

AFTERNOON SESSION

Representative HOLIFIELD. The committee will be in order.

There will be a slight change in order of the witnesses by agreement. We will ask Dr. Western to be the first witness. Dr. Forrest Western of the Division of Biology and Medicine of the Atomic Energy Commission will be speaking on the subject of delayed fallout, the behavior in geological and physical processes and the mechanisms by which delayed fallout enters into the biological processes and reaches man.

Dr. Western, we are happy to have you with us.

STATEMENT OF DR. FORREST WESTERN, DIVISION OF BIOLOGY AND MEDICINE, ATOMIC ENERGY COMMISSION[1]

Dr. WESTERN. Thank you, Mr. Holifield. I believe at this point what I will say will mark a transition in the general nature of the discussions from a discussion of the largely physical and chemical processes which are involved in the production of the radioactive material and the factors which enter into the biological considerations. So this would start the item which on your outline is marked "Topic VIII." I believe this is the correct number. In topics VIII and IX we will plan to cover this entire subject, and my remarks perhaps should be considered in the light of introductory remarks to the papers which will follow.

Representative HOLIFIELD. Dr. Lyle Alexander, then, will take topic IX?

Dr. WESTERN. Topic VIII, I believe. I believe this is the correct numbering, according to the outline, with Dr. Eisenbud, Dr. Kulp, and Dr. Revelle on topic IX.

Before I start my remarks, I would like to do two things. First I would like to express my personal pleasure at the manner in which the hearings have been conducted until now. I have enjoyed very much the questions which you and others have asked the various witnesses. They have at times been very penetrating and very searching. At the same time they indicate a much greater understanding of the highly technical detail that is involved here than one normally finds on the part of people who are not routinely engaged in studies of this kind. I hope that what I have to say will add to the general understanding of the subject.

I have prepared a brief statement which does review a number of things which have already been discussed and which does mention a number of things which will be discussed.

Before I start my prepared statement, I would like to ask permission to submit to you for introduction into the record some statements by Dr. Norman S. McDonald, of the atomic energy project of the University of California at Los Angeles.

At the invitation of your staff, Dr. McDonald has submitted these statements, but I believe he submitted them through us or asked that we submit them for him rather than submitting them directly.

If you wish I shall be glad to identify the parts. If not, I will be glad to give you the copy.

Representative HOLIFIELD. Will you please identify the parts at this point.

Dr. WESTERN. Dr. McDonald has identified his statements in relationship to the outline for the hearings which had been provided.

His first statement has to do with the possibilities for water treatment for the removal of strontium. This is topic VIII.

---

[1] Date and place of birth: August 25, 1902, Purdin, Mo.; education: bachelor of arts, Central College (Missouri), 1924; master of arts, University of Missouri, 1926; doctor of philosophy, University of Wisconsin; University of Pittsburgh, 1933; work history: Lincoln Memorial University, Harrogate, Tenn, professor of physics and head of physical sciences, 1935–42; University of Minnesota, lecturer (physics), 1942–44; Tennessee Eastman Corp., senior physicist, April 1944 to September 1944; Fercleve Corp., Director Laboratory No. 1, 1944–45; Oak Ridge National Laboratory, Assistant Division Director, 1945–51; AEC, Washington, D. C., health physicist, Division of Biology and Medicine, 1951—. (Submitted by the Atomic Energy Commission.)

His second statement has to do with the calcium model as a basis for predicting strontium 90 behavior. This is identified in the outline as topic IX (C).

His third statement is on the deposition in man, variations of strontium-90 level, which he identifies as topic IX (D).

His fourth statement, predicted occurrence from weapons test fired in 1957, topic IX (F).

In addition, there is a group of 11 references upon which some of the statements made are based.

Representative HOLIFIELD. Without objection Dr. McDonald's statement will be inserted in the record. (See p. 720.)

The Chair might state that similar treatment of our subject matter has been requested from a number of scientists who found it impossible because of their duties to attend these hearings. We felt that this would be a matter of supplementing the oral testimony and would give us a complete coverage of the subject as we can get at this time.

You may proceed, sir.

Dr. WESTERN. Thank you.

In these hearings on The Nature of Radioactive Fallout and Its Effects on Man, previous witnesses have discussed the nature of radioactivity and of radiation, and the production of radioactivity in large quantities in the fission process—both in the operation of nuclear reactors and in the detonation of nuclear weapons. The movement of the debris from nuclear weapons has been traced from the time of formation until it is deposited on the surface of the earth.

We are now entering a discussion of the processes by which fallout deposited on the surface of the earth enters the human food chain, either as the result of direct deposition on the surface of vegetation or in the normal uptake of the various chemical elements by vegetation from the soil. In these hearings, our principal interest in considering the movement of radioactivity from nuclear weapons through the human food chain is that of relating quantities of fallout to possible radiation effects in humans.

However, in the event of nuclear warfare, as evident from the discussion this morning, we will be interested also in the possible destruction of animal life, particularly of those animals which represent a major source of food to surviving members of the population.

In the case of local fallout, Dr. Dunning has discussed factors which relate the fallout to levels of radiation from fission products on the ground and some of the factors which determine the sizes of the doses of radiation which may be received by persons in areas of local fallout.

In this connection, he has observed that, during early periods of time after the fission products are produced; the principal hazard to man to be anticipated from exposure to fallout is from radiation originating in radioactive materials outside the body.

Both our knowledge of the extent to which fallout materials may be expected to enter the body by inhalation and ingestion, and observations of actual human uptake of radioactive materials under conditions of heavy local fallout, indicate that for weeks and, perhaps months, after the detonation of a nuclear weapon, the inhalation and ingestion of fallout material will be less important than radiation from fallout in the immediate vicinity outside the body. The length

of time for which this might continue to be true under conditions of actual warfare would depend upon such factors as the protection against external radiation afforded by shelter, upon precautions taken to avoid dust in air used for breathing, and upon sources of food and water.

At this point I would like to depart from my prepared text and discuss in a little more detail the considerations here.

In the inhalation of radioactive material we are interested in radiation exposure to the lungs from material which may be introduced into the lungs and remain there for some length of time. We are interested in radiation to the gastrointestinal system from materials which are brought up from the lungs by normal physiological actions, swallowed, and passed down through the gastrointestinal system.

In this connection we are particularly interested in the large intestine, since, as the material goes down, we have progressive concentration of radioactive material in the material in which it is contained. This results from removal of water from the feces as they pass through the colon.

A second interest which does not depend upon the gross activity of the material which is swallowed but upon the activity of specific radioisotopes contained in this, is the concentration of radioiodine in the thyroid and the consequent irradiation of the thyroid.

This is of particular interest because the thyroid is a very small organ. It is an organ of 20 grams, which is somewhat less than an ounce. While the amount of radioactive material which enters the thyroid is not large, the radiation dose due to the relatively high concentration is comparable to that which would be experienced by the lungs and that which would be experienced by the large intestine. These are all doses which at times for a week or so after the detonation are perhaps of the order of 10 percent of the dose which one would expect to receive from outside the body.

In this connection, if I may, Mr. Chairman, I would like to discuss a little bit farther the question which was raised in Dr. Dunning's discussion this morning about the comparative hazards due to radiation from radioactive materials within the body and radioactive materials outside of the body.

We have no reason to think that any tissue of the body recognizes whether or not the radiation which passes through it comes from within the body or from outside the body. Our interest in making these comparisons is simply in comparing radiological doses to the various tissues.

Perhaps I should go back and explain more precisely the two types of quantities in which we are interested.

In speaking of irradiation of the body, our primary interest is in the absorption of energy of radiation by the tissue itself. This, of course, is related to the amount of radioactive material from which the radiation is emitted. If we take radioactive material into the body, as I believe you pointed out this morning, it is concentrated in various tissues of the body. I have mentioned the case of concentration of radioiodine in the thyroid. We will discuss at considerable length during the hearings the next day and a half the concentration of strontium in the skeleton. These are all normal physiological processes.

When we speak of a dose of 1 roentgen, as in the case of X, or gamma radiation to a tissue of the body, we are not talking about the amount, the total amount, of energy that is absorbed by the body, but we are talking about an intensity of absorption—an absorption per unit of mass. So when a body is subject to a whole body dose of 1 roentgen, we mean that each portion of the body also receives 1 roentgen of radiation. If I expose 1 finger to 1 roentgen, that applies to the finger only. If I expose 2 fingers to 1 roentgen, each finger gets as much as before. We are not dividing the dose between the tissues but we are talking about the intensity of the dose to the tissue. I think this may have been a point of confusion this morning.

Representative HOLIFIELD. I am glad you cleared it up. Let me further try to clarify it in my own mind. Does the 1 roentgen have a different effect on different organs, tissues, or skeleton of the body?

Dr. WESTERN. I would like to say at this point that those of us who discuss these subjects come from many different disciplines of science. I personally am a physicist. I might say that up until this point practically all of the people who have spoken are from the physical sciences—physicists, meterologists, and so on—and while all of us feel we know as much about medical effects as the next man on the street and like to talk about them, we hesitate at times to answer questions of this sort.

I have, however, been spending the last 10 years in trying to understand the medical and biological points of view as well as the physical points of view in problems of this sort, and I will give you tentative answers to the biological problems which I am discussing with the reservation that as you go along you will check my answers against those of medical specialists who will appear later in particular connection with these questions. I give you the answer at this point only for your guidance in following the discussion.

It is true that various tissues have various degrees of radiosensitivity. In this respect, our biomedical people will tell you that the blood-forming organs of the body are among the more sensitive. Perhaps there is no point in enumerating them at this time. Of the ones which I mentioned, the lungs and thyroid are generally considered to be less sensitive than others. I might point out, and this is something which you can readily understand, that in talking about how serious a large radiation exposure is we are interested not only in the sensitivity of the organ but we are also interested in how vital the organ itself may be to the functions of the body.

For example, a man can get along very well without a thyroid. If his thyroid is completely ablated by radiation, he can still under normal conditions at least proceed to get along fairly normally with daily administration of dessicated thyroid or thyroxin. However, this may or may not be true after a nuclear war. Persons with inadequate thyroids would be in serious difficulty if they had no way of supplying the deficiency.

On the other hand, bone cancer has a high probability of being fatal. So when we are talking about the relative hazards due to radiation, we are interested not only in sensitivity of tissue, but we are also interested in the functions of the organ that is involved and the nature of the injury.

Let me say very briefly, then, as Dr. Dunning was saying this morning, in measuring the relative hazard to various tissues of the

body, if we neglect for the moment differences in sensitivity we do get a rough measure by considering the total radiation dose that a particular tissue might get.

Let me come back to the specific question that was asked this morning.

If the whole body is given a dose of 100 roentgens, this means that the skeleton as well as other portions of the body receive the same dose. You will say I am oversimplifying the question because the dose cannot be uniform throughout the body, even from penetrating gamma radiation, because there is some absorption and the surface gets more dose than the skeleton does, and so on, so when we talk about a uniform dose of 100 roentgens this is, in effect, an idealization. But nevertheless it conveys a concept.

If the skeleton only receives 100 roentgens from material within the skeleton, this is the same dose to the skeleton as before as far as the physical factors are concerned. From the biological point of view, one may say that the impact on the body is somewhat less than it would have been in the first case because it is perhaps better for only the skeleton to have received the dose than for the whole body to have received the dose.

There are other differences, however, which biologists may discuss. The question arises as to whether or not the biological effects of a certain amount of energy absorbed from beta radiation are exactly the same as those from the same amount of energy absorbed from gamma radiation outside of the body. This is the relationship to which Doctor Mills referred yesterday as the relative biological effectiveness of various amounts of radiation. We may say in this case we are talking about finer points. Let me say, for example, without making an authoritative statement, that the differences we are talking about are less than would be represented by a factor of 2. I would say considerably less, but I am just trying to give an order of magnitude here.

You asked also this morning about the relationship of a sunshine unit to dose to the skeleton. The statement which I am going to give you is taken from a study made by the National Academy of Science in their report, "The Biological Effects of Radiation," which they issued last year and with which you are familiar. There it was estimated that the radiation dose from 100 sunshine units in the body is equivalent to a lifetime dose of approximately 20 rep. The energy absorption from this dose is equivalent to that from 20 roentgens.

When we are talking about sunshine units in the body, we are talking about a ratio of strontium to calcium. If I may use the units, 1 sunshine unit equals 1 micro-microcurie of strontium 90 per gram of calcium in the skeleton. By 1 micro-microcurie I mean one-millionth of one-millionths of 1 curie. I think the curie was defined for you yesterday as 3.7 time 10 to the 10th disintegration per second of radioactivity. We are not talking about how much radioactivity is in the body. We are talking about how much strontium 90 is maintained in the skeleton at a uniform concentration for a lifetime when we make this comparison.

I should say further for clarification that we are not really interested in the fact that the material is in the body. As I will point out later, strontium itself is a natural constituent of the body. We have in the body something of the order of seven-tenth of a gram of strontium 90. When we are talking about a sunshine unit, for example, I am not in a

very good position to tell you how much we mean compared to seven-tenths of a gram. If I were to start dividing this up into smaller and smaller fractions I would have to take about one-hundredth of one-millionth of one-millionth of a gram of Sr 90 in order to describe a sunshine unit. This is a very small number. We are talking about quantities of material which in themselves are far to small to be of importance to the issue. We are interested only in the fact that the atom emits radiation which is absorbed in the tissues.

I would like to discuss also another portion of your question this morning. You asked, does not the fact that this is stretched out over a lifetime mean that it is more hazardous than if this all occurred at one time? This is a question to which we can't give an answer We are talking about a radiation dose which may be received over a lifetime. At the very low doses in which we are interested here we are not in a position to say whether or not it makes any difference to the individual whether the dose is received in a very short period of time by the tissue or whether it is spread out over a very long time. We do for acute effects, as was discussed this morning, observe tissue repair. At the levels we are discussing now we cannot say whether the dose is more hazardous or less hazardous if it is given in a short period of time.

Returning to the remarks I have prepared:

After longer periods of times, months or years, hazards which may be presented by the residual radioactivity contained in the fallout are primarily due to fission products which may be taken into the body by inhalation or by ingestion. This change in relative hazard of fallout inside and outside of the body follows from changes in the composition of the residual radioactivity with time. In the present discussion, I shall review briefly some of the physical, chemical, and biological factors which determine the relative imporatnce of the various radioactive materials produced by nuclear weapons and the various conditions under which one may be more important than another.

I apologize to you for the repetition contined in these next two pages, but I will go ahead and read them because they do summarize some of the things we have been discussing earlier.

If we examine the atoms of the chemical elements, as they exist in nature, we find that in some cases the atoms of a particular chemical element are all identical. In other cases, the atoms of particular elements can be classified into two or different groups on the basis of differences in the weight or mass of the atoms.

Most of the chemical elements have nonradioactive atoms of at least 2 different weights, and some have as many as 7 or 8. The atoms in a particular weight group are said to be an isotope of the chemical element. The literal meaning of the word "isotope" is "in the same place." It is used to express the idea that the atoms are different but occupy the same place in the periodic chart of chemical elements.

An example of some of the isotopic and chemical properties of interest in a study of fallout is afforded by the chemical element, strontium. Although strontium occurs throughout nature, and was discovered more than 150 years ago, until a few years ago it was perhaps best known as the chemical element used to produce a brilliant red color in fireworks. Aside from this, its principal use has been in the refining of beet sugar. The normal quantity of strontium in the skeleton is

about 0.7 grams, about 0.1 percent of the calcium content of the skeleton.

As strontium occurs in nature, it consists of four isotopes, strontium 84, strontium 86, strontium 87, and strontium 88. The numbers used to designate these isotopes indicate the approximate weights of the atoms in the various groups relative to the lightest atom in nature, that of the common isotope of hydrogen, H–1. In other words, the mass of an atom of strontium 88 is 88 times that of an atom of hydrogen 1. The atoms of all of these isotopes are stable; that is, not radioactive.

The half-dozen isotopes of strontium resulting from nuclear fission are all unstable or radioactive. All of them undergo radioactive transformation into isotopes of the chemical element, yttrium. This process of radioactive transformation is usually referred to as radioactive decay, and the atoms resulting from the transformation are called decay products. Three of the radioisotopes of strontium 90 resulting from fission decay so rapidly that, in a fallout situation, they will have become isotopes of yttrium before the fallout reaches the vicinity of personnel and are consequently of no interest here. Our interest in the isotopes of yttrium into which they decay depends upon whether or not the atoms of these isotopes are radioactive and upon other factors considered later in this discussion.

The atoms of a particular isotope decay at such a rate that a definite fraction of the total number of atoms will undergo transformation in a specified period of time. The time required for half of the atoms of a radioisotope to undergo radioactive transformation is called the radioactive half-life of that isotope. Radioactive half-lives may vary greatly from one radioisotope to another. Here I am speaking of radioisotopes in fallout or in the original fission product produced by the bomb—some are as short as a fraction of a second, and some are as long as millions of years.

Even though one cannot say just when the last atom of a particular quantity of a radioisotope will be transformed into an atom of another, the large number of atoms involved in any measurable quantity of a radioisotope does make it possible to state the average lifetime of the total number of these atoms. In each case, the average lifetime of the atoms is approximately 1.4 times their half life. This relationship has led to confusion from time to time because sometimes we speak of half lives and sometimes we speak of average lifetimes. Unless one distinguishes between the two there is an apparent discrepancy of this factor of 1.4.

Similar language is frequently used in discussing such matters as the length of time which the atoms of a particular chemical element may be retained in the human body, or the length of time which the debris from a high-yield nuclear weapon may be retained in the stratosphere. For example, it is sometimes said that the half life of strontium in the human skeleton is several years. Here I am talking of a number of the order of perhaps 7, 8, or 9 years. I prefer not to state it more precisely than that. This concept of a half time is valid only to the extent that the process to which it is applied involves a rate of decrease proportional to the quantity present. In the case of strontium and calcium in the skeleton, while it appears that this may not be strictly true, use of the term half life or half time gives a rough idea of the quantitative relationships involved.

Returning to a consideration of the relative hazards of the radioisotopes of strontium, we observe that strontium 91 has a half life of 10 hours, strontium 89 a half life of 53 days, and strontium 90 a half life of 28 years. About as many atoms of one as of another are produced in fission. For example, in a nuclear reactor, about 5 percent of the fissions give rise to strontium 89, 5 percent to strontium 90, and 5 percent to strontium 91.

In giving these numbers let me say I am using very roughly approximate numbers. These numbers may vary from about 5 to 6. In fission processes that involve different energies of neutrons and different fissionable materials, there is also some variation. So these numbers are sufficiently accurate for purposes of this illustration.

In a nuclear weapon the fractions are generally not greatly different. If we were to introduce large quantities of these radioisotopes into the human body in the relative proportions in which they are produced in fission, the strontium 90 would be the least hazardous of the three, and strontium 91 which is seldom mentioned in connection with fallout, would be the most hazardous. I will put it on this basis: I have as many atoms of strontium 91 as I have of strontium 89 or strontium 90. The atoms of strontium 91 would decay with a half life of 10 hours, or the average time they would spend in the body would be about 14 hours. These atoms would deliver to the skeleton after deposition—deposition would take place within a matter of an hour or two—all of their energy of disintegration in a relatively short time. Half of it would have been delivered after about 10 hours.

On the other hand, the atoms of strontium 90 would remain in the body until they either underwent radioactive decay or until they were eliminated by natural processes. These processes are both very slow but perhaps a third or more of the atoms would be eliminated before they decayed at all.

So the total dose delivered to the skeleton by the strontium 91 would be larger than the total dose delivered to the skeleton by strontium 90.

There are other differences which I will not discuss in detail. Strontium 91 has a somewhat more energetic beta ray than strontium 90, although it is comparable. Strontium 91 is also a gamma emitter, whereas strontium 90 is not. In addition to the dose delivered to the skeleton, strontium 91 would also deliver a sizable dose to the gonads, to the blood-forming organs, and other tissues of the body.

However, in an actual fallout situation, the strontium 91 is of interest only for a day or so, and then primarily because of the contribution which the gamma radiation it emits makes to the total radiation emitted by radioactive materials outside the body. By the end of 3 days, 99 percent of the atoms of strontium 91 will have decayed into yttrium 91. Yttrium 91 is also radioactive, but the chemical properties of yttrium are such that a much smaller fraction of its atoms enters the human body and a still smaller fraction is retained in the body. I say "enter" here in the sense of being absorbed into the body in the case of inhalation or in the case of ingestion. Yttrium, if ingested would pass readily through the gastrointestinal system with a much smaller uptake by the digestive processes than of strontium 90.

Similar considerations apply in comparing the relative hazards due to strontium 89 and strontium 90. In a local fallout situation, for several weeks after fallout the strontium 89 would constitute a hazard

equal to or greater than that of the strontium 90. This would be true either for the inhalation of fallout or for the ingestion of fallout retained on surfaces of vegetation or as an impurity in other sources of food and in water. By the end of about 6 months there is less than 10 percent as many atoms of strontium 89 as of strontium 90, and the relative hazard is correspondingly small.

In the case of long-range fallout, following the storage of bomb debris in the stratosphere, it is clear that our interest is in radioisotopes of which the half lives are measured in years rather than in days. Under these conditions, strontium 89 is, of course, of no concern.

Before entering into a more detailed discussion of relative physical and chemical characteristics, I would like to make it clear that our ultimate interest in the atoms of any particular radioisotope depends only on the radiation dose which they can give to the body. It is meaningless to say that one radioactive material is more hazardous than another except as, under a specific set of conditions, it can deliver a larger radiation dose to the same part of the body or a comparable dose to a more critical part of the body. For example, if we are considering the biological effects of beta emitting material uniformly dispersed through the mineral structure of the skeleton, we are not specifically interested in whether a given quantity of radiation is emitted by a radioisotope of barium, or of calcium, or of phosphorous, or of strontium, or of some other element of which the chemical properties are not inconsistent with the concept of uniform dispersal in the bone. We have every reason to believe that under such a condition, the biological effects produced by a given concentration of strontium 90 in the bone would be no greater or no less than those produced by that concentration of calcium 45 required to give the same dose of radiation to the bone.

After an oversimplified statement of this sort, I realize that I am subject to an argument which is not a primary argument in considerations of this sort. But because it illustrates a point which I would like to make, I will give the argument here.

We are talking here about radiation of the bone—beta radiation—from two different isotopes. When I speak of quantity of radiation I am speaking primarily of the amount of energy absorbed by the bone—the amount of energy which goes into ionization of the tissues of the bone—and consequently of the number of ions that may be formed in a tissue.

As a second order effect, it is true that one can detect very small differences under some circumstances between the biological effects of one beta particle which produces a certain density of ionization, and another which produces a slightly different density of ionization. The average density of ionization depends upon the average speed with which the beta particle moves through the tissue and that in turn depends on the initial energy of the particle.

I am making an oversimplified statement. I can be challenged on the statement.

This gives rise to the impression that I do not know what I am talking about. I had written a qualifying statement of this sort in the discussion. It was suggested that the idea is too complex to put into a discussion of this sort, and so I left it out. But in view of the nature of the things upon which people generally agree in a discussion of this sort, and the nature of differences of opinion, I do believe it is valuable

at this time to point out that in discussing a problem as complex as the one which is being discussed here in these next 2 or 3 weeks, that one must consider the importance of areas of agreement and areas of disagreement.

I am sorry that Senator Anderson is not present. Senator Anderson in the opening session asked about opinions of scientists which are diametrically opposite. So far as I know, in this field there are no opinions of scientists which are diametrically opposite. We disagree on many things. If we stop to analyze the areas of disagreement in general they are secondary issues. I think, if I might use a very homely illustration, I am reminded of a couple of men determining whether or not they would prefer to own a Cadillac or a Chrysler. The man who wants the Chrysler would say, "Look at those beautiful fins!" The man who owns the Cadillac has some beauty, too. But the men who owns the Chrysler can point out that the Chrysler Corp. has mentioned recently that at 90 miles an hour these fins give a certain amount of road stability. These people have diametrically opposite ideas about these automobiles, but I think both would agree that both the Chrysler and the Cadillac are good automobiles.

So when we talk about disagreement, I think we have to look at the manner in which the disagreement arises and consider whether or not the scientists who are disagreeing are disagreeing on their pet theories or whether they actually have fundamental disagreements as far as the overall picture is concerned.

Chairman DURHAM. What you are saying today, doctor, was true a thousand years ago in physics.

Dr. WESTERN. Yes. I am not speaking as a scientist here at all. This is commonsense.

Chairman DURHAM. You certainly talk like one.

What I was trying to point out is that the disagreement is no greater than it was a thousand years ago in theoretical physics.

Dr. WESTERN. No. One does not need to go very far in history to find disagreements of a similar nature. You will recall, Mr. Durham, I know, that it has not been very many hundreds of years ago since people felt it was extremely dangerous to sleep with the windows open. You may remember in much more recent history there were people who wanted to outlaw bathtubs for certain reasons. You can think of a great many instances in history in which we have had these very serious disagreements.

Chairman DURHAM. I was not taught strontium-emitting rays when I was dispensing drugs over the drug counter.

Dr. WESTERN. Yes; you undoubtedly dispensed uranium over the drug counter, too.

Chairman DURHAM. Yes.

Dr. WESTERN. We will pass on.

Chairman DURHAM. Yes.

Dr. WESTERN. Our interest in general fallout, as distinguished from local fallout, originated in an effort to evaluate hazards to general populations as a result of large-scale nuclear warfare.

I would like to say at this point that we were interested in this problem several years ago. My first connection with this problem was when I came with the Atomic Energy Commission in 1951. But there were already studies underway preceding that by at least 2 years which had indicated very generally the sort of thing which I am

discussing today. The studies had not gone nearly as far as we have carried them in the last 5 years, but they had outlined the general principles involved here.

With the important exception that vastly greater quantities of fallout would be involved and the hazards would consequenlty be vastly greater, conditions of fallout on noncombatant populations in warfare would be very similar to the general fallout from testing of nuclear weapons.

Under these conditions, we are interested in conditions in which the longer lived radioisotopes from fallout are present in the soil and on vegetation and, in varying concentrations, in food, water, and air.

Depending upon their respective chemical properties, quantities of the various radioactive isotopes in the soil will enter the normal metabolic processes of vegetation, and quantities of the various radioisotopes in or on vegetation will enter into the normal metabolic processes of animals and humans. In this respect, it should be observed that plants and animals do not distinguish between radioactive isotopes and nonradioactive isotopes of the same chemical element. Some of the biochemical factors involved will be illustrated by discussion of strontium as an example.

In this connection of not distinguishing between radioactive and nonradioactive isotopes I would like to mention some misconceptions which have occurred in popular statements during the past year or two. There is a feeling, for example, that some of the tissues of the body have the property of concentrating radioactive materials. These properties of which we are speaking are natural properties of the tissues.

Of course, the skeleton concentrates calcium, and because of the similarity between strontium and calcium, of course, the skeleton concentrates strontium. If the strontium and calcium contain some radioactive strontium, that of course would be concentrated to the same degree. At least the radioactive strontium will be concentrated to the same degree as the nonradioactive strontium in the skeleton.

Chairman DURHAM. Do you care, Doctor, to say what in your opinion creates that affinity?

Dr. WESTERN. It is not an affinity. The question is more fundamental than that. Why is calcium an essential constituent of the human body or the plant? It is one of the essential biological constituents. If we admit the human having a skeleton, it must be composed of certain minerals. The only way that the skeleton can obtain these minerals is to concentrate calcium and phosphorous from the various sources of food and water that the animal takes in.

In the case of strontium 90, the chemical properties of strontium, including strontium 90, are so nearly the same as those of calcium that one has difficulty in separating the two. The chemical properties are so nearly the same that the strontium atom can fit into the same position in the crystal structure of the bone as the calcium can. I believe this is also true of crystal structures in nature. If you look at a calcium compound in nature and in a natural crystal you will find here and there a strontium atom occupying a position which otherwise might have been occupied by a calcium atom. The apparent chemical affinity of the skeleton for strontium 90 is just a combination of two facts: The essential need for calcium in the process of

building the bone and the fact that strontium is so closely similar to calcium chemically.

There are other essential needs for calcium in the diet, as you know, but some of our biomedical people could discuss this problem at considerable length.

In addition to radioisotopes of strontium, we may be interested in one or more of the several other radioisotopes, including iodine 131, barium 140, cerium 144, plutonium 239, and cesium 137. Consideration of the physical and biochemical properties of other radioisotopes in fallout makes it very evident that these radioisotopes are of much less interest than strontium 90 except for periods of less than a few months after they are produced. From a given detonation, the relative number of atoms of a radioisotope entering the metabolic processes of the body will depend upon the following factors:

1. The relative number of atoms of the radioisotope formed in the fission process. The percentage of fissions giving rise, directly or indirectly to a particular radioisotope, is called the fission yield of that radioisotope. The fission yield of strontium 90 is about 3 percent or 4 percent. I used earlier a figure of 5 percent, but I did mention it varies from 1 process to another. It is somewhat less, I believe, in many of our nuclear weapons than it is in the reactor fission. This is due to several reasons.

Chairman DURHAM. The yield in the reactor process has a higher content of strontium 90?

Dr. WESTERN. Generally, yes, by a factor of less than 2.

The highest fission yields are about 6 percent.

That applies to, I believe, fairly well either the yields in a reactor or a nuclear weapon. This is an order of magnitude.

2. The principal method by which fallout enters the body is in the diet. Some fallout enters the diet as a result of retention on the surface of vegetation, without entering the soil. For example, a very little of the cesium 137 in the human diet is believed to come by way of the soil. I make this statement with some reservation. I believe this will be verified in the remarks which will be made either by Dr. Langham or Dr. Anderson tomorrow or Monday depending upon which day this is given.

Most of it comes from meat and milk, as the result of retention on the vegetation eaten by the animal with some possible contribution from surface water used by animals.

The extent to which any particular radioisotope will enter the diet, then, may depend upon several factors. Many radioisotopes, such as the rare earths and plutonium—the rare earths include yttrium, which we discussed earlier, and cerium 144 discussed in the first part of this paragraph—are taken up in comparatively small amounts from soil by plants; and also in small amounts by animals from the diet. As a result, quantities ingested by humans are very small, and the quantities assimilated by the human are still much smaller.

Take the extreme example of plutonium. In the case of inhalation, it is considered perhaps one of the most hazardous of the elements with which we work. Perhaps a considerable fraction, several percent, of the plutonium inhaled, if it is inhaled in sufficiently small particles, is retained in the lung for some time. It may be dissolved in the blood stream and a fairly good fraction deposited in the skeleton.

But when we are talking about plutonium on the ground, as orders of magnitude, perhaps the ratio of uptake of plutonium as compared to strontium by plants from the soil is something of the order of 1 to 1,000 or 1 to 10,000. When the human or animal digests the food we have a similar ratio of about the same order of 1 to 1,000 or 1 to 10,000. So if we had equal portions or equal numbers of atoms, let me say, of plutonium and strontium 90 in the soil, we would get roughly about a million times as much strontium in the skeleton as we would plutonium.

Chairman DURHAM. But suppose that cow had a dose of strontium 90—say 300 roentgens—and I drank the milk, then where do we go from there? Of course, it is a small amount we are talking about now that is assimilated into the digestion of the cow. Let us reverse it and give her a big dose.

Dr. WESTERN. What we are interested in is amounts which could be considered hazardous. I noted from the discussion this morning about fallout in milksheds and so on that there is a considerable amount of misunderstanding as to the importance of milk in determining the hazard of fallout to humans. As far as I am aware, people who get their calcium from milk are in at least as good a position as people who do not get their calcium from milk. This may be discussed in more detail by subsequent speakers.

But since you raised the question, let me mention that the human has to have calcium to exist. If the human has no milk, he gets his calcium from other sources. He gets it from vegetation. If there is strontium accompanying the calcium—strontium 90—in the vegetation, he gets the strontium. He may not have as much per gram as from milk, but he will eat enough vegetation to supply his calcium needs.

Following the process of uptake of strontium 90 through milk, the milk is in effect a barrier to the uptake of strontium 90.

To some extent, at least in the animal, and possibly in the plant, there is what we call discrimination between strontium and calcium. We have indicated that strontium and calcium are very alike chemically. We have also indicated that there are differences. I said it is difficult to separate calcium and strontium, but of course we can do it. We are talking here about two things which behave as they do because they are very much alike, but also have sufficient differences to behave differently.

In carrying calcium and strontium from plant to the milk, the cow appears to discriminate against calcium by a factor—let me just give an order of magnitude and it may be larger or smaller—of $\frac{1}{10}$. By this I mean to say that the ratio of strontium to calcium in milk is less—there is less strontium 90 or natural strontium, it doesn't make any difference—per gram of calcium in the milk than there is in the food which the cow eats.

Representative HOLIFIELD. Is that discrimination against the element or is it lack of availability of one element as compared to the other?

Dr. WESTERN. No. Suppose we consider the natural food of the cow. Let us take an American example. Roughly in the vegetation which the cow eats there is perhaps 1 atom of strontium for 1,000 atoms of calcium. Let us use larger numbers. Let us say 1,000 and 1 million. The cow, however, secretes into the milk a smaller ratio of strontium-calcium. For each million atoms in the milk there may

be only of the order of 100 atoms of strontium rather than 1,000 which one finds in the cow's diet. So one is better off by drinking the milk than by eating the forage which the cow eats. Of course, one does not eat forage, but what I mean to say is that if you get your calcium from vegetation you do not have this barrier in between the vegetation and your own diet.

Representative HOLIFIELD. But by the same token when the children and babies drink more milk than eat hay they get the strontium quicker, do they not?

Dr. WESTERN. I ought not to get into this type of discussion.

Representative HOLIFIELD. Let us leave the detailed discussion until later on.

Chairman DURHAM. Are you saying, Doctor, in the process of the cow assimulating through ingestion and the machinery of producing milk that if she had a dose of 300 roentgens that would not necessarily mean that there would be 300 in the milk.

Dr. WESTERN. We need to go back and talk about quantities of strontium 90 which in a cow would produce perhaps to the skeleton a radiation-dose equivalent to 300 roentgens. I am saying this. If one assumes, as a first order of magnitude, that the deposition of the strontium-calcium in the skeleton of the cow is the same as that of a human—this is only an approximation because I think one could expect, for example, that in a cow giving large quantities of milk one is going to get differences in the metabolism as compared to other animals—if one makes this assumption, then what I have said is equivalent to saying that if this amounts to a dose of about 300 roentgens in the skelton of a cow in a specified period of time it would amount to about one-tenth of that in the human who drinks the milk in the same length of time. This is because the cow is in effect shielding the person who drinks the milk from a certain amount of the strontium which he would have gotten if he obtained his calcium from vegetation instead of milk. This is a real effect.

I oversimplified the thing again because I promised myself I would not get into these biological discussions and I have friends back here in the audience who are having fits back here because there is another factor which I have not considered and that is that the actual deposition in the skeleton of strontium appears to depend upon whether you take it from milk or vegetation. This is something which I am neglecting altogether.

Let me disclaim any expertness in this field at the moment. I tried to give you a little bit of guidance as to what I mean.

At least let us say that as far as the elements are concerned, the fact that the child drinks the milk does not constitute any greater hazard than if he got his strontium and calcium from other sources, and to my mind it constitutes a lesser hazard. The cow is actually a protection.

Chairman DURHAM. I am assuming if the cow does not get a big dose.

Dr. WESTERN. Here we are talking about a matter of degree. Of course, when you start into a discussion of this sort you begin to say "if." Let us assume that what we are talking about is that the child is eating vegetation from the garden and that the cow is eating vegetation from a pasture across the fence. So we have comparable situations here. Then all we are talking about is what is the relative

hazard to the child of taking the calcium and strontium from the milk or from the vegetation.

Representative HOLIFIELD. The only thing I can draw from that, Doctor, to bring it down to a practical understanding of the layman is this. What you have said has amounted to this: The cow in eating the pasturage would retain a certain amount of strontium in her own skeleton, but that there would be a certain amount of it in the milk and it would be transferred into the diet of the infant. At the same time, if there was lettuce or radishes or things like that growing in the garden that had a direct deposit of strontium and the child ate that, it would get a bigger dose comparatively speaking by getting it direct without having it go through the process of the milk machine.

Dr. WESTERN. I think this is true.

Representative HOLIFIELD. But nevertheless we cannot draw any comfort from the fact that children do drink a lot of milk and eat very few vegetables directly and therefore they would get the maximum amount of this material probably from milk because that is the major part of their diet at early ages, at least.

Dr. WESTERN. May I make another remark?

Representative HOLIFIELD. Is that too oversimplified?

Dr. WESTERN. May I make this remark which I think bears on your statement. This may be a little bit abstruse but I believe it is worth stating.

When you say we cannot draw any comfort from this, let me say that the thing that we are interested in from the point of view of hazard to the individual is the amount of strontium 90 which we find in his skeleton. Let us consider a child—my own son for example, or my own daughter—who has a certain amount of strontium 90 in his skeleton. This is my primary consideration: How much does he have now? How much will he have? It makes very little difference to me, except as it enables me to predict in the future, how it got there. My fundamental interest is how much. I don't draw comfort from the fact that he got it one way or from another, or I don't say unfortunately this and this is true. We are relating a certain amount of strontium 90 in the skeleton to a certain amount that has been produced in weapons tests. It is this relationship which is fundamental regardless of the method.

This is another case of the sort of thing which I mentioned earlier, it doesn't make any difference whether two scientists disagree as to how it got there. The proof we are interested in the point of biological evaluation is that it is there.

Representative HOLIFIELD. I recognize that. The only reason I have tried to simplify it was that I have known times before when statements were made and immediately in the press or some public utterance a statement was made based on that, that we do not have to worry about milk because it has such a little amount of strontium in it compared to vegetables. I thought I was trying to bring it down to a practical matter of at least my understanding.

Dr. WESTERN. I agree with you completely in that. In any case we are interested in the amounts which are getting into the skeleton of the human.

Representative HOLIFIELD. You may proceed.

Dr. WESTERN. 3. Most of the radioisotopes resulting from fission are so unstable that by the time the fallout reaches the human they

have been largely transformed into stable isotopes, and are of little or no interest.

4. Finally, the biological effect of a particular isotope will depend not only upon how much enters the body but upon the distribution and retention in the body. If it is concentrated in a relatively small portion of the body, the radiation energy absorbed by that portion will be correspondingly higher. This is true, for example, in the case of radioiodine in the thyroid which consists of only some 20 grams of tissue. Because of the small size of the thyroid, the amount of radioiodine needed to destroy the thyroid by radiation is relatively small. If a large fraction of the atoms of a radioisotope are eliminated from the body before they undergo radioactive transformation, the radiation dose is correspondingly smaller. This is true, for example, of cesium 137, which has a half-life of 27 years but spends only about 200 days, on the average, in the body.

A survey of the many radioisotopes produced by fiission discloses that under current fallout conditions, because of some combination of the factors just enumerated, relatively small fractions, compared to strontium 90 and cesium 137, can reach the body. If the elapsed time is much smaller, as in the case of local fallout, some of the shorter half-lived radioisotopes become more important, especially strontium 89, with a half life of 52 or 53 days; iodine 131 with a half life of 8 days; and barium 140, with a half life of 13 days. At still earlier times, iodine 133, with a half life of 22 hours, may contribute an appreciable fraction of the dose to the thyroid. However, under these conditions, both experience and theoretical studies indicate that the critical consideration is the exposure of the body to gamma radiation from fallout outside the body.

The rare earths, such as cesium 144 and plutonium, are not only absorbed from the gastrointestinal tract of the animal and human to a much less extent than are iodine, strontium, and cesium, but their uptake by vegetation is very low.

The biochemical behavior of cesium in the body is very similar to that of the relatively abundant chemical element, potassium. Perhaps as much as 50 percent of the cesium 137 in the diet is assimilated and distributed through the soft tissues of the body. The average length of retention in the human body is about 200 days.

The evaluation of the relative importance of strontium 90 and cesium 137 is made difficult by the fact that the effects of exposure of the whole body to radiation, either from cesium within the body or from gamma-emitting materials outside the body, are different from the effects of exposure of the skeleton to the radiation from strontium 90. In the case of whole-body exposure of a large population group to radiation, one is interested in the increase in the rate of genetic mutation as well as the possibility of an increase in the incidence of leukemia, while in the case of a radioactive material in the skeleton the principal consideration is the possibility of an increase in the incidence of bone cancer. One cannot expect to find very much agreement between various individuals as to the relative importance of these very different effects. These questions are scheduled for discussion in these hearings at a later time.

Representative HOLIFIELD. Thank you very much, Dr. Western. You have given us quite a comprehensive comparison of the different radioactive isotopes which can be taken up by the body in this field,

at least, and I am sure this will add a great deal to our understanding of the importance of the different ones.

I believe we have one question here.

In the last paragraph in your discussion, in the comparison between radioactive particles being emitted within the body and outside of the body, there was no implication that strontium 90 is not associated with an increase of leukemia as well as bone cancer, was there?

Dr. WESTERN. That is a question which should properly be asked later. It was my intent to imply, as a matter of guidance, that the effect which I would expect from strontium 90 would be bone cancer. The probability of leukemia would be, relatively, sufficiently small to be of no concern. This is a question that should be asked of the biomedical experts.

Representative HOLIFIELD. Thank you very much, Dr. Western.

Our next witness will be Dr. Lyle Alexander from the Department of Agriculture. He will continue the discussion on delayed fallout and the behavior in geological and physical processes and the mechanisms by which delayed fallout enters into the biological processes and reaches man.

Dr. Alexander, we are happy to have you with us today. Will you proceed, please.

STATEMENT OF DR. LYLE ALEXANDER, UNITED STATES DEPARTMENT OF AGRICULTURE[8]

Dr. ALEXANDER. Thank you, sir.

Representative HOLIFIELD. Are you making this presentation on behalf of yourself, Mr. Reitemeier, and Mr. Seymour?

---

[8] Born at Athens, Tex., in December 1903. Received the B. S. degree from the University of Arkansas in 1928. That same summer he joined the U. S. Department of Agriculture (Bureau of Chemistry and Soils) as a junior soil physicist. He completed the Ph. D. (in chemistry) at the University of Maryland in 1935 while continuing laboratory research in the Department. Researches in soil science became increasingly broad and significant in both the laboratory and in the field. He was steadily advanced to research positions of greater responsibility. In 1938 he represented the Department at an important international conference on soil chemistry in Finland. After 1945 he had responsibility both for the basic soil research in the Division of Soils, Fertilizers, and Irrigation, and for the service and research laboratories of the Division of Soil Survey of the Bureau of Plant Industry, Soils, and Agricultural Engineering. He continued, however, highly significant personal research in soil science, including pioneer work on the use of radioactive isotopes. In 1951 he headed a successful international mission of scientists, under the auspices of the OEEC of the ECA, for the detailed study of laterite formation in the soils of Africa. His responsibilities for cooperative work with the Atomic Energy Commission increased. In 1950 he received the Superior Service Award from the Department.

Near the end of 1952, the Soil Survey was transferred to the Soil Conservation Service and he continued as Chief of the Soil Survey laboratories and as the Department's principal scientific liaison with the AEC. Except for broad project planning, others took over the details of the work on radioactive isotopes in what is now the Soil and Water Conservation Research Branch of ARS, while he gave increased attention to highly classified research for the Atomic Energy Commission. An important phase of this included researches dealing with the effects of radioactive fallout following bomb explosions, which have required many overseas study missions and field researches.

Besides these researches, he strengthened and reorganized the Soil Survey laboratories to serve the expanded soil survey program in the Soil Conservation Service. He has greatly improved the methods for measuring soil permeability and especially for interpreting the results. He is giving unusually valuable counsel to the leaders within the Service on all phases of soil chemistry and plant nutrition that relate to soil use and conservation. In 1954 he was advanced to his present position as soil scientist, GS-14.

Member and leader in many scientific societies, including the Sigma Xi, the American Chemical Society, the Soil Science Society of America, the American Society of Agronomy, of which he is a fellow, and the International Society of Soil Science, of which he is an officer. Vigorously applied his unusual gifts for sustained, arduous study—in the laboratory, in the field, and in the library—to highly difficult and complex scientific problems. He cooperates easily and effectively with other scientists in his own and related fields, and with nonscientists as well. He has an exceptionally deep sense of his responsibilities as a scientist, as a research administrator, and as a public servant. As a result, he not only carries along and finishes an enormous amount of work of the highest quality person-

Dr. ALEXANDER. Yes, sir. We will cover the rest of your No. VIII in your outline, except for that portion to be covered by Dr. Revelle.

On behalf of Dr. Reitemeier and Dr. Seymour, I wish to express my appreciation for the opportunity of discussing some of these questions involved in radioactive fallout with your committee.

DEPOSITION AND MIGRATION IN SOIL AND TRANSPORT BY SURFACE WATERS

The chemical and physical properties of strontium are closely related to, but systematically different, from those of the essential plant growth element calcium. Hence, a consideration of the fate of the fission product strontium 90 in the earth's geochemical and physical processes becomes a study of the behavior of calcium and the degree to which the heavier strontium ion may lag behind its lighter counterpart.

In a similar manner, the behavior of cesium 137 is related to that of the quite common essential plant growth element potassium, which has a naturally radioactive isotope, potassium 40. The rare earths, on the other hand, have no vital role to play in the nutrition of plants or animals, so far as we know. Since strontium 90, cesium 137, and the rare earths comprise nearly all of the long half-life fission products that might be of concern to man, a consideration of their behavior and that of the fissionable element plutonium will give the picture of the longtime fallout problem.

Calcium in the soil occurs in two forms. The important one to plants and to animal and human nutrition is the fraction that is attached to the surfaces of soil organic matter or humus and of the clay particles of the soil. This is the so-called exchangeable calcium or fraction that can be replaced by other positively charged ions. It is this fraction that gets into man's foodstuffs through plant and animal systems. The other fraction of the soil calcium is found in relatively insoluble minerals and is not of immediate importance to us.

Strontium 90 that has fallen at considerable distances from bomb bursts has been mostly water soluble or has become soluble on contact with most soils. The strontium 90 ions in solution immediately react with the exchange complex of the soil. As a result the strontium 90 is attached to the soil in such fashion that it cannot be readily leached by water but can be taken up by the plant. The newly at-

---

ally, but also stimulates and helps others to work more effectively throughout the Federal Government and in other research institutes. He is in great demand from many agencies as a counselor in several scientific areas. Outstanding contributions have been so many that only a few of the principal ones can be outlined.

A so-called radioactive growth stimulant being offered to farmers was thoroughly tested by Dr. Alexander in a large group of experiments having unusually precise control on several kinds of soil. By proving the material valueless and by promulgating the results (against great pressure) he protected American farmers from a highly active promotional scheme.

Dr. Alexander organized a very fruitful basic research program on the use of radioactive materials in research dealing with soils and plant nutrition, conducted jointly by the Department and the Atomic Energy Commission. He gave immediate leadership to the work for about 5 years. During this time elaborate scientific laboratories, greenhouses, and equipment were developed and installed. Ways were found for using and for measuring precisely levels of phosphorus, potassium, and several other nutrient elements in soils and plants. These methods are now widely used in many research institutes throughout the world and have been critically important to the solution of many heretofore unsolved problems of great significance in soil fertility.

Recently Dr. Alexander has been studying the distribution of radioactive fallout from nuclear explosions. This has involved an unusual combination of detailed knowledge of the chemistry and radioactivity of a whole group of elements, including especially strontium, calcium, and cobalt; of the morphology, chemistry, and distribution of soils; and of the chemical relations between soils and growing plants under different conditions. (Submitted by U. S. Department of Agriculture.)

tached strontium 90 ions become a part of a reservoir of calcium and strontium ions that are almost alike to the plant—not necessarily identical but certainly similar.

If the strontium 90 becomes a part of a large pool of exchangeable calcium and strontium ions, the fraction of it taken up by a plant root is less than if it becomes a part of a small number of ions from which the plant may draw its nutrients. We know of no mechanism by which these exchangeable calcium and strontium ions of the soil can become fixed in a form unavailable to plants. The addition of calcium ions to acid soil increases the size of the pool of calcium and strontium and hence decreases the number of the strontium 90 ions taken up by the plants. This is the basis for methods that have been suggested for decreasing strontium 90 uptake by liberal use of lime on acid soils. At best, these methods may reduce the uptake of strontium 90 by a fewfold.

Calcium and strontium do not readily move downward in the soil by leaching with rainwater. When the water carries appreciable quantities of calcium or hydrogen ions, strontium 90 does indeed move downward but the rate of movement is slow. It is impractical to move strontium 90 from the root zone of our crop plants by a leaching process.

Representative HOLIFIELD. The point you are making there is that once strontium 90 is deposited on our soil where plants and vegetables are grown, that it is very hard to leach it and get rid of it?

Dr. ALEXANDER. Yes, sir. I will mention later some of the tillage practices that will minimize the effect. But it is there and it is difficult to get it out. You can't expect rainwater to leach it out.

Cesium and potassium differ materially from strontium and calcium in their chemical behavior in the soil. In addition to the categories of available and mineral latice ions attributed to strontium and calcium in the soil, there is a third condition or state that falls between these two so far as the plants are concerned. In this condition the cesium and potassium ions are neither readily available to plants nor are they completely inaccessible to them. Depending on the level of potassium in the exchangeable form, some of these ions may become available to the plant. In soils containing certain types of silt or clay particles, the potassium may become a part of a mineral in which it is unavailable to plants and cannot be leached from the soil. While we do not know as much as we would like to know about the behavior of cesium in soils, it seems reasonable that it would be more tightly held than the potassium. And this does indeed seem to be the case. Plants take up but little cesium from the soil and it is difficult to remove it from the soil by replacement with another ion.

It would appear, then, that cesium 137 falling on the soil in amounts equal to the strontium 90 will be a lesser constituent in the plants that are used by man and animals for food and feed.

The rare earths and plutonium are so tightly held by soil and so little taken up by plants that they will be of slight or no concern to man or animals by entry through roots. It has been shown that some plants—particularly trees—can take up and differentiate between some of the rare earths. However, the total amounts involved are so small that they are of no importance in the fallout problem.

If we accept rainfall as the principal agent for depositing fission products on the earth's surface, one conclusion is that the deposition

in a given area is uniform—it falls on the just and the unjust alike. Since soil movement is one of the main processes by which the land is formed, and man accelerates this movement by cultivating and overgrazing the soil, it is inevitable that part of the fallout deposited in many areas will be moved into lower lying positions. These soils formed at the foot of slopes and in stream bottoms may accumulate larger amounts of fission products than fell on them directly. In the case of thin sheet erosion and subsequent deposition in a lower lying position, the concentration could be many times as high as the area has received on the average through direct fallout. As pointed out above, the elements with which we are concerned are rather tightly held by the soil, and where the soil goes, they go. For the same reason, water that has moved through the soil will have had most of its long-lived radioactive contamination removed.

On the other hand, fission products in water might move through relatively large underground channels in rocks for considerable distances before they were absorbed in the channel walls. For example, as at Arco. Inland lakes that have no exits must accumulate fission products to the extent that these are carried in the water and sediments of the entering streams. Because of the low content of fission products in the irrigation water the amounts entering the Salton Sea at the present time are very small.

While the downward movement of long half-life fission products that we are discussing is slow, there are differences in rate of movement that reflect the capacity of the soil to hold such elements in the ionic state. Sandy soils, for example, will generally have deeper penetration of strontium 90 than will the finer textured silt loams and clays. Mechanisms for penetration of fallout into soil below the surface few inches are the earth mixing due to earthworms and the development of large cracks in some soils during dry weather. When the rains come, surface-soil material flows into the cracks and carries the surface-deposited strontium or cesium downward. In most of our soils that have not been cultivated since 1953, the bulk of the strontium 90—say 75 percent—is found in the upper 2 inches of soil.

The foregoing statements give a basis for conducting a program of evaluation of the total amount of fallout that occurs in a given region. The sampling sites are so situated that they receive no runoff water from higher ground and lose no rainwater by runoff. This requires a permeable soil that is nearly level, and that has enough clay or organic matter to hold on to the strontium ions that reach the soil surface. It is desirable that the soil be in a grass cover, although farm soils that are in rotations involving corn, small grains, and hay crops have proved quite satisfactory.

THE EFFECT OF AGRICULTURAL PRACTICES

As mentioned earlier, farm practices such as leaving sloping ground bare to erosion by water or by wind can move the fallout from where it fell to some place of accumulation. This, of course, makes for nonuniform distribution in an area. The extent of this depletion and concentration has not been determined.

The vertical distribution of fallout in a soil may be altered by agricultural practices such as deep plowing. This changes the position of the fallout with respect to the root zone of the crops. In case

of shallow-rooted crops such as some grasses and many vegetables, the deep plowing may materially reduce the uptake of strontium 90. At best, one can expect only a fewfold change in uptake by the plant from these mechanical soil treatments. Plowing, harrowing, and mixing of soils on which strontium 90 has fallen are generally expected to reduce the uptake of this element due to moving it from areas of higher to lower concentration. Experiments are underway to test this supposition.

The practice of liming has been suggested as a remedial measure for areas having high concentrations of strontium 90. This can be reasonably effective if the amount of available calcium in the soil is very low, such as in some of our unimproved pastures. By increasing the amount of ions similar to strontium in the soil its uptake is decreased. While this is feasible on some soils—and in fact it would benefit many of them aside from considerations of strontium 90 uptake—there are limitations on the heavy application of lime to most agricultural soils. Their productivity for many crops would be jeopardized by large amounts of lime. Such additions or heavy applications of gypsum would lead to imbalance of both major and minor essential elements.

As with mechanical practices, one cannot expect liming to change the strontium uptake by an order of magnitude. Only a fewfold reduction can be anticipated at most. Even less can be said for large additions of fertilizers containing calcium, because the calcium content in them is lower than in lime.

THE EFFECT OF FALLOUT ON WATER SUPPLIES

The fallout on lakes, rivers, and oceans is mixed with relatively large volumes of water and hence is not so concentrated as the fallout that lodges in the top few inches of soil, where plant roots are usually concentrated. These waters, other than the salty ones, have flora and fauna that are in need of calcium. Hence, strontium 90 also is taken up and eventually settles out on the bottom of the lake or in the mud of the river. The moving waters also contain soil or rock powder, and these absorb the strontium 90 so that open waters are not hazards from fallout from atomic tests.

Water that comes from wells or springs has been filtered through soils. The strontium 90 has been largely removed in the process of filtration. For industrial processes that require large volumes of water, containing negligible amounts of radioactivity, open lakes, and rivers might pose a problem. From the standpoint of direct effect on man, waters do not constitute a major source of concern. In case of contamination due to warfare, the strontium 90 could be readily removed from drinking water by water softeners or ion exchange resins.

FOOD COLLECTION AND DISTRIBUTION

In case of atomic warfare, food supplies could be seriously contaminated by strontium 90 and other fisssion products. Material that falls out directly on vegetables consumed by man, could, in some cases, be removed by washing with water or by discarding portions of the foodstuff such as the outer leaves of cabbages or the peelings of

potatoes. Strontium 90 that becomes a part of the plant either by uptake through the plant roots or by assimilation through the leaves from direct fallout cannot be removed from the foodstuff without removal of the calcium also. Milk containing strontium 90 probably could not be made free from this contaminant without simultaneous removal of the calcium and consequently changing the basic character of the milk. Food treatment and processing during wartime conditions could be expected to alleviate only that contamination due to direct fallout.

Alterations of food distribution patterns could be used to lower strontium 90 intake. This might involve bringing in vegetables and milk, which serve as a considerable source of calcium in the diet, from areas that have had little or no contamination. The contaminated areas could be used for growing the foodstuffs that contribute little to the calcium of the body, such as grains and meat. Obviously, this might involve difficult problems, or even be impractical, depending on the size and location of the contaminated and uncontaminated areas. Remedial measures could be evaluated from our knowledge of the occurrence and chemical behavior of calcium and strontium in soils and in food and feedstuffs.

ENTRY INTO BIOLOGICAL PROCESSES

When fallout lodges directly on plants that are eaten by man and beast, all of the radioactive elements which are present in it may be of concern. Strontium 90 and cesium 137 can be metabolized by the plant and become a part of it even though not coming through the roots. The extent to which the rare earths and plutonium would remain on the plant material and be ingested by man and animals is not well known at the present time. It is believed that they are of less concern than strontium 90.

It is possible that most of the cesium found in milk comes from direct uptake through deposition on forage that the cows eat, although it is also possible that surface drinking water could be a major source. A few years ago, when the soil contained less fallout and atmospheric fallout was increasing, a major share of the strontium 90 in forage consumed by livestock was from direct fallout on the vegetation. Since the level has increased in the soil, the indications are that most of the strontium 90 gets into the plant by way of the soil and root uptake at the present time.

Alfalfa grown on two very sandy soils in Illinois derives its calcium from high-calcium subsurface horizons rather than from the plowed layer. In these cases, the uptake of strontium 90 has been very small in comparison to vegetation that obtains its calcium largely from the plow depth, where the strontium 90 occurs. Experiments with black-eyed peas, lima beans, and snap beans at Beltsville, Md., during 1956 indicated that only a small part of the strontium 90 in the vegetation came from direct deposition on the plant surfaces.

Representative HOLIFIELD. May I stop you there, Dr. Alexander, and ask you why this statement could be possible in view of the fact that the number of tests have increased within the last 2 or 3 years and therefore there would logically be a greater deposit from the atmosphere on the surface of the ground and less underneath. Why

is it that the plant is taking up more from below the ground than it is through its leaf?

Dr. ALEXANDER. The amount in the soil has increased. I believe the figures were mentioned this morning from 5 to something like 20 or 25 in this general area.

Representative HOLIFIELD. In other words, the spring plowing takes the deposit that occurs in the nongrowing season and puts it underneath the surface.

Dr. ALEXANDER. Yes, sir. You can plant snap beans and harvest them in 42 days. So the time exposed is relatively short and the amount of fallout during that short period of time is relatively small compared to the total in the ground at the present time.

Representative HOLIFIELD. The amount in the ground has increased by a factor of 4.

Dr. ALEXANDER. Four or five since 1953.

Representative HOLIFIELD. If the number of bomb tests increase and we go on for a series of another 10 years, could we now extrapolate an approximation as to the amount that would be taken up by the vegetables through the soil? Would there be a geometric increase or what type of increase could we estimate that would occur?

Dr. ALEXANDER. It seems to me that if we keep the amount coming out in the air constant and increase the amount of soil, then with another 10 years the amount from direct fallout on the leaf would be insignificant compared to the amount taken from the soil. It must go in that direction.

Representative HOLIFIELD. What would be a reasonable extrapolation for the next 10 years, let us say, in view of the history of the last 3 or 4 years?

Dr. ALEXANDER. Sir, there are some uncertainties. These estimates are based on strontium 89 and strontium 90. There has been uncertainty in the determination of strontium 89. So I do not really know exactly.

Representative HOLIFIELD. That is true about strontium 89, but the facts are pretty well known about strontium 90 with its 28-year life.

Dr. ALEXANDER. Yes.

Representative HOLIFIELD. You could well say that for 28 years from 1954, if we use that as the base year to start—if we want to go back further we could to some of the earlier tests—you would have an accumulative increase, would you not, in the soil?

Dr. ALEXANDER. Yes, sir. In the Chicago milkshed area from 1953 to 1955 approximately the increase in strontium 90 in vegetation was proportional to the increase in the soil.

Representative HOLIFIELD. Then the next thing that would concern us would be: Would that amount of increase be to the point where it would be detrimental, and if so, how much? Or would it be so infinitesimal that it would not be of any concern?

Dr. ALEXANDER. All I could do would be to make a prediction as to how much would be there if so much more falls out. You could double the amount in the soil and perhaps approximately double in amount in vegetation. As to what would be harmful to man I would rather someone who is a biologist or medical man pronounce on that.

Representative HOLIFIELD. We will have testimony on that factor later.

Dr. ALEXANDER. Yes, sir.

Representative HOLIFIELD. When we talk about increasing 4 or 5 times and then as the years go by increasing 10, 15, 20 times the amount that was in the soil in the year 1954, this is the thing that alarms people, because they have no way of evaluating what that increase amounts to in terms of detrimental effects. We hope that there wil be some evaluation from the scientists if we are to the point where we can evaluate that in the later hearings.

Chairman DURHAM. Doctor, is there not a limit to plant life as to the amount of any type of chemical substance they will absorb and take into the plant?

Dr. ALEXANDER. Mr. Durham, in this case I believe the amount in terms of weight is so small that I don't believe one would approach any kind of saturating point.

Chairman DURHAM. Having had a little experience with farming, especially in vegetables, I think we always felt even the use of fertilizer—which is a different thing—you go through the same process of assimilating it into the plant life. I was always taught that a plant would assimilate so much chemical substance of whatever kind.

Dr. ALEXANDER. That is right.

Chairman DURHAM. It has a food limit just like if I do not want 2 pieces of pie I will eat 1.

Dr. ALEXANDER. If you have 4 pieces of pie sitting in front of you you will take only 1 instead of all of them.

Chairman DURHAM. Of course, the danger period would be as to the amount absorbed by the plant. When you reached that point you could be concerned.

Dr. ALEXANDER. The amount absorbed by the plant will depend upon the amount of other similar ions that are present. So it depends on whether or not the quantity added of fission product is a measureable amount compared to what is already there.

I believe Dr. Western or somebody spoke of million—millionths of a gram.

Chairman DURHAM. It is not going to run up the beanstalk unless there is something there that attracts it.

Dr. ALEXANDER. The cow thinks it is calcium. It can hardly tell the difference between calcium and strontium. So it needs calcium and takes up the strontium.

Representative HOLIFIELD. To carry the illustration further, it is true that one plant in its lifetime will be limited to the amount that it takes up. But if people continue to eat plants, let us say, from contaminated ground, it becomes accumulated in the human being in the period of 28 years, does it not?

Dr. ALEXANDER. Yes, sir.

Representative HOLIFIELD. So the hazard of the one lifetime of a plant is not the thing that we can stop at. We have to carry it on to its final resting place as far as the human being is concerned.

Dr. ALEXANDER. We will take up a little later the matter of discrimination factors and the ratio between the strontium calcium in the vegetation compared to what will come out in the human bone.

Representative HOLIFIELD. You may proceed.

Dr. ALEXANDER. Since 1953, the strontium 90 found in vegetation has increased in proportion to the increase in the total amount of strontium 90 that has fallen out on the soil on which the vegetation grew. The uptake of strontium 90 by shallow-rooted plants is not so erratic as for the deep-rooted plants such as alfalfa and sweet clover. These deep-rooted plants may be getting the bulk of their calcium near the surface, if growing on an acid soil that has been limed. On the other hand, as mentioned above, the alfalfa may be drawing its calcium from a deep horizon and consequently getting little strontium 90 from the deposition of fallout on the surface. Soils having abundant calcium in the soil zone containing the fallout will produce vegetation of lower strontium 90 content than comparable soils with low calcium levels.

Cesium 137 seems to be taken up more readily by plants from solution cultures than from soils. Apparently, the cesium ion is so firmly held by the soil surfaces that it is not readily available to plants. Likewise, the rare earths and plutonium are little taken up by plants from soils; hence, these elements become of interest only to the extent that they are deposited directly on foodstuffs or in water supplies.

Soil-to-plant discrimination factors have been of considerable interest to those working with fission products that get into the food chain. Evidence for a discrimination against the uptake of strontium relative to calcium is conflicting. Some data based on tracer experiments have indicated that there might be a 2-to-1 factor against strontium uptake.

Menzel and Heald made 2 studies designed to measure discrimination between stable strontium and calcium, 1 in the greenhouse and 1 in the field. In the greenhouse experiment with 10 crops on 4 soils, the average discrimination factor for stable strontium and calcium between soil and plant was 0.7. Under field conditions at 93 sites in 11 States no discrimination, on the average, was found between the ratio of calcium and strontium in alfalfa and wheat and the ratio in the exchangeable form in the soils on which they were grown. There may be no single answer to the problem, but it seems that one should not count on a large discrimination factor for strontium.

All evidence available points to a rather large discrimination factor for the uptake of cesium from soil. Menzel found a factor of 50 for the reduction of uptake of cesium relative to acid-soluble potassium.

It should be emphasized that discrimination factors, where they exist, are strictly applicable only to equilibrium conditions. Probably none of our soil root zones has been brought into equilibrium with the recently added fission products. Thus, it is difficult at this time to make calculations based on uptake found under field conditions. At the present time in the United States, we can find forage that has strontium 90 to calcium ratios that are lower than, higher than, or equal to the ratio of these elements in an exchangeable form in the surface horizons of the soils from which the forage came. These variations are due to unequal distribution of the fission products and exchangeable calcium in the soil, and to uncertainties as to what constitutes the root zone of these particular plants.

UPTAKE AND RETENTION IN ANIMALS AND MAN

Food and water comprise the main mode of entry of radioactive constituents of delayed fallout into the bodies of animals and humans. In the period immediately following the deposition of fallout from the atmosphere, a substantial fraction of the ingested contaminants may originate in fallout deposited directly on edible vegetation. In the case of animals this would involve primarily forage grasses and legumes, and in the case of man, vegetables. With the passage of time, and with the discarding of directly contaminated food, however, the relative importance of the fraction which is absorbed from the soil through plant roots becomes preponderant. Accompanying this change with time is a shift in the composition of the radioactive atoms contaminating feed and food, from a mixture of a number of isotopes to one eventually predominated by strontium 90, and, to a lesser extent, by cesium 137.

For a period of days following a heavy deposition of fresh fallout, iodine 131, which has a half life of 8 days, may be of importance in direct contamination of vegetation. Radioiodine is selectively concentrated in the thyroid gland, where excessive accumulations cause cancer and cell destruction. Injury to the gland may not be detected until long after the iodine has decayed.

Plutonium and the rare earths are absorbed only very slightly from the gastrointestinal tract, so that these elements are not relatively important biologically from the standpoint of ingestion of fallout The fraction of these atoms that does enter the blood system becomes selectively concentrated in the organic matrix of forming bones. After they are deposited there, they undergo only a slight decrease in concentration with time. Since the half life of plutonium 239 is 24,000 years, this means that no substantial reduction of radiation from this isotope will occur during the life of the affected individual.

Cesium 137 becomes distributed in the body similarly to the essential nutrient element potassium. It occurs in muscle tissues, other soft tissues, and the blood. Because it emits gamma rays also, it subjects the entire body to radiation. The rate of clearance of cesium from the body is relatively so high that the continuous ingestion of substantial amounts from food and water is required to maintain a high body burden.

Strontium is readily absorbed from the gastrointestinal tract, somewhat less readily than is calcium, and a large fraction of that absorbed is accumulated in the crystalline mineral portion of bones, similarly to calicum. This deposition in the bone occurs partly by an exchange replacement of calcium ions located in the surfaces of the mineral crystals and partly by bone growth. The concentration of strontium 90 in the bone relative to calcium is not uniform unless the ratio of strontium 90 to calcium in the food has remained reasonably constant during the entire period of development of the skeleton. At any one time, the skeletal deposition of currently ingested strontium occurs preponderantly at sites of active bone growth and bone tissue reforming. The radiation at these sites from strontium 90 from its daughter by decay, yttrium 90, is a potential cause of bone cancer and damage to the blood-forming tissues. The likelihood of this injury in general would increase with the skeletal concentration of strontium 90, and with the length of its retention in the bones. It would be

greater for children than for adults whose skeletons were completely developed. The average period of retention in the human body is several years. Because the radiological half life is 28 years, the main cause of reduction in radioactivity from strontium 90 during the period of residence in the body is the process of elimination of the strontium atoms from the body.

Although strontium is closely similar to calcium in behavior, it moves somewhat more slowly through metabolic processes and membranes in animals and man than does calcium. The magnitude of this discrimination may be small in any one metabolic process, but by a succession of such processes, each one magnifying the preceding discrimination by a small factor, substantial discrimination between the two elements may ultimately be effected. The discrimination factor for a specific process is defined as the ratio of strontium to calcium in the product divided by the ratio of strontium to calcium in the reactants. The observed ratio for a sequence of processes, for which the individual discrimination factors may or may not be known, is the ratio of strontium to calcium in the final product divided by the ratio of strontium to calcium in the reactants of the initial process.

Representative HOLIFIELD. Doctor, going back to the previous paragraph, you plainly state that the degree of absorption of the body depends upon the growth of the bone tissues. You point out that in the case of children whose bones are growing there would be a greater percentage of strontium 90 absorbed than in adults. Is that correct?

Dr. ALEXANDER. Yes. As I understand from discussions that have been had in a grown person there is some bone turnover. There are points of bone that are regrowing and others that are decomposing. To the extent that the regrowth of bone is taking place, either from an injury or from a natural repair, you would be taking in some from your diet. But the child is laying down all of its skeleton.

In other words, it is growing more constantly. The bone in a child is getting so many more pounds every year, whereas with a grown person the weight may stay the same but he has a certain amount of turnover.

Representative HOLIFIELD. It is building the size of its bone skeleton as well as repairing the part that dissolves?

Dr. ALEXANDER. That is right.

Representative HOLIFIELD. There is no question about this fact, is there? I mean the scientists are agreed upon this point?

Dr. ALEXANDER. I believe so; yes, sir.

Representative HOLIFIELD. I ask that for a very definite purpose. We realize in all testimony that most scientists take into consideration systematic error or even personal error in making their conclusions. The reason I wanted to ask that question was to find out if there was any appreciable controversy on that point.

Dr. ALEXANDER. I don't believe so.

Representative HOLIFIELD. You may proceed.

Dr. ALEXANDER. Recently experimental studies with humans and various animals, based on different approaches in many instances, have established a number of the important discrimination factors and observed ratios, with commendable precision. The techniques used in these experiments have included:

(*a*) Radioactive strontium tracer versus stable natural calcium;
(*b*) Radioactive strontium tracer versus radioactive calcium tracer; and
(*c*) Stable natural strontium versus stable natural calcium.

The field sampling program for strontium 90 also has provided valuable information. Drs. Cyril L. Comar, Daniel Laszlo, and Norman S. MacDonald, and their colleagues, are among those who have made important experimental contributions to the attack on this problem.

The discrimination values mentioned here apply strictly only when the ratio of strontium to calcium in the diet remains constant during the entire period of development of the skeleton. On a diet not containing milk or milk products, the strontium to calcium ratio in the bones of rats, goats, and humans has been found to be about 0.25 to 0.30 of that in the diet. When milk is the source of the calcium and strontium, the ratio in the bones of rats and humans will be about 0.55 of that in the diet. Some components of milk increase the relative absorption of strontium from the gastrointestinal tract. The milk produced by cows and goats from their normal diet will have a strontium-to-calcium ratio of about one-tenth to one-seventh of that in the diet.

Representative HOLIFIELD. May I ask you to stop there to clarify this statement above:

> When milk is the source of the calcium and strontium, the ratio in the bones of rats and humans will about about 0.55 of that in the diet.

Let us assume that there is a hundred units of strontium in the diet. Your point there is that the body would only absorb 0.55. In other words, just a little over half of 1 percent of the gross amount of intake?

Dr. ALEXANDER. That is relative to laying down an equal amount of calcium. These units are in terms of the strontium relative to calcium.

Representative HOLIFIELD. Then I am wrong in my interpretation of what you save said there. That refers to the percentage it would take up in relation to the calcium that would be taken up.

Dr. ALEXANDER. Yes, sir.

Representative HOLIFIELD. How much of the calcium would be taken up?

Dr. ALEXANDER. That would depend on the stress. If it were a calf on a low-calcium diet, he would use maybe 90 percent. If it had an excess of calcium it would use a smaller percent. It would make that discrimination.

For a gram of bone growth, there would be 0.55 as much strontium as was in the gram of calcium that went into the food. So it is a reduction of half as far as the strontium uptake is concerned.

Other things being equal, sir, your question would be right. If the animal is using all the calcium in its diet, then your statement would be essentially right, that for a gross intake of so much it would only mean half as much was taken up.

Representative HOLIFIELD. So we can at least draw this comfort from the fact that the amount that was ingested by the animal would not be transferred either to the meat or the milk, and then in turn transferred by human ingestion to the human body. Am I right in that interpretation?

Dr. ALEXANDER. Perhaps I was thinking of a growing animal rather than one that was lactating. I believe the system is a little more complicated in a cow depending on the calcium. If she is very low in calcium she may be drawing calcium from the bones in order to get the amount she needs to make the milk every day.

As far as the meat is concerned, strontium and calcium are not a factor. They are a factor in the bone and the milk.

I believe in general lactating animals will give preference to the production of milk. Nature in general tends to make the milk all of the same composition. If you give a cow a low- or high-calcium diet, she will produce milk of the same composition. But the utilization of what goes through her would be quite different percentagewise.

Representative HOLIFIELD. How would that differ in the case of a hen and an egg?

Dr. ALEXANDER. I am afraid you have me over a barrel because I do not know too much about the calcium to make hen eggs. The only thing I know is that if a chicken is too low in calcium they produce an egg which has very little calcium and it is a soft egg without a shell. I personally don't know very much about the nutrition of chickens.

Representative HOLIFIELD. We will go on then, if you do not know that.

Dr. ALEXANDER. Studies with rats and rabbits indicate that the strontium-to-calcium ratio in the fetus would be about one-half of that in the body of the mother. Experiments with lactating goats suggest that the ratio in the milk produced would be about 0.38 of that in the blood plasma. Absorption from the intestines and urinary excretion appear to be the processes causing the major discrimination against strontium in nonpregnant nonalactating mammals.

The appropriate discrimination factors and observed ratios can be combined mathematically to estimate the overall discrimination between strontium and calcium in the vegetation and in human bone. To be valid, these calculations must be based on reasonable assumptions concerning the fractions of the calcium intake derived from various sources—for example, cow's milk, vegetables, and the mother's body. For newborn infants, the predicted overall discrimination has been estimated to range from a minimum value of 0.10 to a maximum value of 0.045. For 6-month-old children, the estimated range is from a minimum discrimination of 0.13 to a maximum of 0.041. For children over 6 months of age and adults, the estimated minimum discrimination value is 0.20 and the maximum 0.09. It is apparent, therefore, that the metabolic processes in humans and animals are favorable to a substantial reduction in the hazard of strontium 90 to man, as compared to the level of contamination of the vegetation in the food chain and of the soil on which it is grown.

Uptake by marine organisms: In the consideration of the uptake of fallout by marine organisms no recognition is made of the difference between early and delayed fallout. In fact, most quantitative observations have been on the distribution of local fallout. One important difference might be expected, that delayed fallout would be small particles, which would remain in the surface waters.

The distribution of fallout in the ocean is dependent upon the location and time where fallout occurs and the dispersion following fall-

out. Dispersion is mainly by water movement, but also can be by transport in plankton, fish, or other organisms.

The depth in the ocean where the fallout particles occur has an important bearing on distribution. The water from the surface to the thermocline is often called the stirred layer, as it is assumed that this water is being mixed constantly. Below the thermocline, which occurs from 100 to 200 meters below the surface, the water is stratified and slow moving. Therefore, it may be assumed that small fallout particles will remain in the surface and may be transported great distances, whereas larger fallout particles will be moved horizontally while passing through the stirred layer, but relatively little once they are below the thermocline. Some support is given to this assumption by the fact that deep water samples from the vicinity of the Eniwetok test site just previous to the Redwing tests in 1956 were radioactive from previous fallout, which suggests that some radioactivity from earlier tests had not removed far horizontally.

Ultimately, the fallout in the surface water becomes a part of the major current system of the ocean and moves in a gyro around the entire basin. In the Northern Hemisphere the circulation is clockwise, and in the Southern Hemisphere counterclockwise. In the vicinity of the Eniwetok test site, the North Equatorial Current moves westward to the Philippines, where the current splits, with most of the water flowing northward to become the Japanese Current. Off the coast of Japan the current turns eastward to flow across the Pacific Ocean and arrives off the coast of North America at about 50° north latitude; there it flows southerly, and later westwardly, to complete the cycle.

In 1955, 1 year after Operation Castle, a survey was made to determine the distribution of radioactivity in the plankton and water of the North Equatorial Current in the western Pacific. Starting near the test site, the survey moved westward to the Philippines and thence northward to Japan. Activity, or other than from naturally occurring isotopes, was widespread and of low level, with the highest values found off the Philippines, a distance of 2,500 miles from the test site. Values for water ranged from zero to 537 disintegrations per minute per liter and for plankton from 3 to 140 disintegrations per minute per gram wet weight. As a comparison, the radioactivity in sea water from the naturally occurring isotope, potassium 40, is about 540 disintegrations per minute per liter. Although this fallout probably remained in the North Pacific circulation system, it would become increasingly difficult to detect because of the continuing processes of dilution and radioactive decay.

The radioactivity of water and plankton samples from an area contaminated by fallout, shortly after bomb tests, was determined on two series of Redwing samples. One series was collected during the operation and the other 6 weeks after its conclusion. During this period of time the maximum water value decreased to 16 percent and the plankton value to 2 percent of the earlier values.

The transport of radioactive isotopes away from a contaminated area by marine organisms is possible. One way this could happen would be for migrating fish to prey upon radioactive organisms while moving through a contaminated area. Another, and probably a more important way, is associated with the daily vertical migration of

plankton. The diurnal migration of plankton to near the surface during hours of darkness and to deeper waters during hours of light is well known. There was evidence of this situation in samples collected near Bikini, just previous to Redwing. At the surface plankton was radioactive but the water was not, while in deep water both were radioactive. It is thought that this was a result of plankton becoming radioactive in the deep water and then moving toward the surface.

Marine organisms can acquire radioctive isotopes directly from the water in which they are living or indirectly by ingestion of other radioactive organisms. The acquisition of radioisotopes directly from the water may be either by absorption or adsorption, but this is of little importance from the point of view of the food chain. An example of a food chain leading to man starts with the one-celled plants, then leads to the one-celled animals, to the small many-celled animals, to small fish, to large fish, such as a tuna, and finally to man. There may be a few, or there may be many links in the food chain, and radiosotopes may enter the chain at any point.

Marine organisms, similar to terrestrial plants and animals, differentially select and retain minerals in their bodies, and can concentrate elements from sea water. The selection of an element depends upon the physiological demand of the organism for the element and the availability of the element, and to some extent, of chemically similar elements. The greatest concentration will occur when the demand and availability are greatest, and vice versa. For example, because zinc is relatively scarce in sea water and there is a physiological demand for this element by fish and shellfish, zinc in an available form that is added to sea water is rapidly removed and concentrated by fish and shellfish. A similar example is that of the alga, *Asparagopsis*, for iodine. On the other hand, when strontium, which is naturally more abundant in sea water, is added to sea water, its concentration by most marine organisms is not great.

The plankton samples collected during and after the Redwing operation were analyzed for the radiosotope composition. The isotopes found include strontium 89 and 90; barium 137 and 140; cerium 144; praseodymium 144; ruthenium 103 and 106; zirconium 95; cobalt 57, 58, and 60; zinc 65; iron 59; and trivalent rare earths. There were differences in the isotopes found in the plankton samples collected in different areas. One reason for this difference is that plankton is composed of many groups of organisms, each with an affinity for specific isotopes.

For this same reason, the concentration factor of radioactivity by plankton in relation to the water of its environment varies greatly. A concentration factor of a thousand or greater is often observed. Because plankton does concentrate fission products and other radioisotopes, measurement of the radioactivity in a plankton sample is a convenient method of determining the presence of radioactive isotopes in the water.

In fish most of the elements expected from fission are found and also the nonfission products formed by neutron irradiation of bomb and tower metals, manganese 54, iron 59, cobalt 58 and 60, and zinc 65. Often the nonfission products predominate. It has been mentioned that little strontium is found in most marine organisms. A land crab does accumulate strontium 90 in the liver and shell, whereas marine crabs contain little strontium 90.

A program of radiobiological monitoring has been a part of all test series in the Pacific Ocean. Samples of fish, invertebrates, birds, plankton, water, soil, algae, and terrestrial plants and animals have been collected from the ocean, lagoon, reef, and islands of many places in the Pacific Ocean. Some have been visited only once, while others many times. Except for the immediate vicinity of the test site, biological contamination by fallout in the Pacific Ocean has been very slight.

Representative HOLIFIELD. Thank you very much, Dr. Alexander. That was quite a task for you to go through that, particularly at the speed that you went through it. But I think you have given us a lot of very valuable information for our record, and we appreciate it.

Our next wtiness is Dr. Roger Revelle, Scripps Institute of Oceanography, University of California.

As a fellow Californian, sir, I welcome you to the witness stand.

STATEMENT OF DR. ROGER REVELLE, DIRECTOR, SCRIPPS INSTITUTE OF OCEANOGRAPHY [3]

Dr. REVELLE. Thank you, Mr. Holifield. I have some charts that we might put up.

Representative HOLIFIELD. Very well.

Dr. REVELLE. I have a prepared statement which I would like to submit for the record.

Representative HOLIFIELD. Without objection, your prepared statement will be received for the record, and you may proceed to summarize in any way you desire.

(The statement referred to follows:)

STATEMENT BY PROF. ROGER REVELLE, SCRIPPS INSTITUTION OF OCEANOGRAPHY, UNIVERSITY OF CALIFORNIA

1. At present the measurable radioactivity in the oceans consists of the natural radioactive elements and artificial radioisotopes from tests of atomic weapons.

2. In the future, additional radioactivity may become introduced into the ocean from the use of atomic weapons, accidents to nuclear powered vessels, accidents to nearshore reactors, from the oceanic disposal of atomic waste, and in coastal areas, from land runoff. Some evidence that this latter effect now exists in the La Jolla region is shown on table 1.

---

[3] Scripps Institution of Oceanography. Date and place of birth: March 7, 1909, Seattle, Wash. Education: A. B., Pomona College in 1929; Ph. D. in oceanography, University of California in 1936. With the exception of service in the Navy during and immediately after World War II, his entire career has been spent at the University of California's Scripps Institution of Oceanography, of which he became director July 1, 1951. On staff of Adm. W. H. P. Blandy in Operations Crossroads in charge of oceanographic measurements. Organized resurvey of Bikini in 1947. Fellow of American Association for Advancement of Science, San Diego Society of Natural History, Geological Society of America; member, American Meteorological Society, Sigma Xi, Society of Limnology and Oceanography, Geological Society of Washington, Western Society of Naturalists, Cosmos Club, Men's Faculty Club, Berkeley, American Association of Petroleum Geologists, and American Geophysical Union. President for 1956–59 of the section on oceanography of the American Geophysical Union. President of special committee on oceanographic research of International Council of Scientific Unions; chairman, National Academy of Sciences Committee on Biological Effects of Atomic Radiation in Oceanography and Fisheries; member for North America of International Advisory Committee on Marine Sciences of UNESCO; member, Committee for the International Geophysical Year of the International Association of Physical Oceanography; the Panel on Oceanography of the National Committee for the International Geophysical Year; and Divisional Committee for Mathematical, Physical, and Engineering Sciences of National Science Foundation. In 1954, Dr. Revelle received the Albatross Medal of Swedish Royal Society of Science and Letters for outstanding achievements on oceanography, especially in deep-sea research. Honorary doctor of science from Pomona College. Elected to National Academy of Sciences April 28, 1957. (Submitted by witness.)

3. Natural radioisotopes exist everywhere, but they are much lower in the sea than in any other region of the earth where life exists. Therefore, artificial radioactivity can modify the marine environment to a somewhat greater *relative* extent than it can the land environment. Due to the great volume of the sea, however, the *absolute* change in radioactivity will be small. Table 2 shows the natural radioactive nuclides in the sea, and it can be seen that the natural radioactive background of the ocean is almost wholly due to radiopotassium and is very low. In consequence, marine organisms and sailors normally experience very low exposure to external radioactivity.

4. In addition, because man is a land animal, the oceanic radioactivity usually has less *direct* effect on him than does radioactivity on land. Table 3 shows the total natural exposure of man and other organisms in different environmental situations.

5. The principal mechanisms by which artificial radioactivity in the ocean may represent hazards to man are through the marine products—the animals and plants of the sea that are eaten by man and his domestic animals or employed as fertilizers.

6. At present, fallout from weapons tests is the only significant source of artificial radioactivity in the oceans. Table 4 shows activities of some oceanic organisms collected off California in April 1957.

Most of the fallout from United States weapons tests falls on the oceans. In the first place the large weapons tests occur there and the close-in fallout comes down directly on the sea. In addition, the oceans cover 71 percent of the earth's surface and of the widely distributed stratospheric fallout from both United States and Russian tests, up to 71 percent falls into the sea.

The proportion of fallout occurring in the close-in region varies from zero for a high airburst to perhaps one-half for a ground surface burst of a large weapon, and 90 percent for an underwater burst of a nominal atomic bomb.

7. In the sea this fallout radioactivity mixes rapidly to an appreciable depth. Since land fallout ends up on a surface, the concentration of fallout per volume of material tends to be greater on land than on the ocean.

It is known that the very close-in fallout from ground explosions penetrates the ocean very rapidly, part of it penetrates through 100 meters in less than 20 minutes. For water and air bursts and outside the very close regions for surface land bursts, the fallout is mixed throughout the upper 50 to 150 meters within a few days after arrival. In the trade wind region this mixing is complete in 30 hours.

The rate at which fallout becomes distributed below the surface depends on two factors: the size of individual particles containing the radioactivity and the rate of vertical mixing in the sea. The rate of settling is of primary importance for particles larger than eight hundredths of a millimeter in diameter while the rate of mixing of the water itself dominates, at least during the first few days, for particles with a diameter of less than 0.04 millimeter. Within a few miles of a big surface burst over shallow water or land, the particles average about 0.2 of a millimeter in size and settle at a rate of more than 200 meters per hour. The concentration of radioactivity not far above the "front" of settling particles is fairly uniform. At greater distances, where vertical mixing of the water predominates, the lower boundary of the radioactivity layer deepens at first at a rate of 5 meters per hour, and below 20 or 30 meters at a rate of 2 or 3 meters per hour, until the bottom of the mixed surface layer at 50 to 100 meters is reached. At this depth the rate of mixing greatly diminishes and the radioactive layer may not become much deeper for periods of several weeks.

8. Because of this rather rapid mixing, the fallout, once it gets in the ocean, presents a much smaller *direct* hazard than fallout on land owing to the shielding by the immense mass of water with which it has mixed.

It can easily be shown that because of this vertical dispersion of the fallout, and the absorption of radiation coming from below the surface by the water, the radioactive hazard to a human being at or above the surface is less than one hundredth of that which would exist over land after the first half hour from the cessation of fallout. It is only about 20 percent of the land hazard during the first half hour.

9. Both close-in and early (or tropospheric distant) fallout fall in a relatively small part of the ocean. The radioactive substances are moved by currents and by mixing to other areas in concentrations that are high in comparison with a final distributed level. Thus the ocean currents represent a mechanism of transport of fallout materials. Subsequent concentrated fallout of radioactivity from the same site commonly is not added to the same water mass and hence, unlike

the case of land detonations, concentrations are not increased. During the process of transport the waters are mixed laterally and to some degree vertically and the concentration of radioactive materials decreases. As an example of the concentrations to be expected at moderately great distances from the Pacific Proving Ground in a few months after a weapons test, we may cite the results obtained by the Japanese Shukotsu Maru expedition shown in the accompanying chart.

10. Over a long term of perhaps 200 to 400 years the material falling to the surface waters of the sea is diffused throughout the whole volume of the ocean, which is more than 40 times the volume of the surface layers.

11. The surface layers, into which fallout rapidly mixes, are of the greatest importance to man as they contain most of the living plants and animals that he harvests, and which may take up radioactivity from the water.

12. There is communication between the deep and surface layers along shores and in certain other areas where the phenonmenon known as upwelling occurs. In these regions, several factors are worthy of note. The upwelling waters are rich in nutrients and a subsequent heavy growth of plankton results. This plankton growth is the primary foodstuff upon which the major fisheries of the world depend. Hence in a region where the surface is contaminated by radioactivity, these primary food substances, derived in part from deeply submerged waters, may contain a somewhat lower level of activity than plankton in a region where upwelling does not occur. On the other hand, disposal of radioactive materials, accident to nuclear-powered vessels, or the use of deep ASW weapons, which may introduce radioactivity below the mixed layers will, through the process of upwelling introduce radioactivity directly into the surface food chain.

13. In addition, marine organisms migrate vertically more than 1,000 feet between day and night and from this migration there may be appreciable transport of radioactive material that is in the food chain, particularly because of the capacity of the organisms to concentrate certain isotopes. In the cruise of the *Taney* (see reference, United States Atomic Energy Commission, 1956), it was apparent that the activity of the organisms is not only influenced by the immediate water in which they are found but also by the underlying and adjacent water masses.

14. The ocean is a concentrated salt solution, which contains nearly all of the chemical elements either in solution or suspension, just as ordinary rock and soil contain all of these elements. However, the concentrations and state of these chemical elements in the sea differ in several significant respects from those in the soil. For example, radium and its daughter products are almost completely absent from ocean water whereas they are more common in rock, and almost all elements exist in a form wholly available to organisms, unlike the soil and rock where many elements are tied up in unavailable silicate complexes. The concentration of various elements in the sea is shown in table 5.

15. Organisms tend to concentrate certain of the more dilute elements and many chemically identical or similar artificially radioactive substances are highly concentrated by marine plants and marine animals. An example of such concentration is the case of Co–60 and Zn–65.

Two long-lived radioactive isotopes that are present in fallout, but are not fission products, are cobalt 60 and zinc 65. Cobalt 60 has a half life of 5.3 years, zinc 65 has a half life of 250 days. Both are beta and gamma emitters. Although the total quantities of these substances produced by the explosions is small compared to the fission products they are very highly concentrated in marine food animals. Amounts as high as one-third of a microcurie of cobalt 60 were found in the liver of an 8-inch clam from a location in the Marshall Islands about 80 miles from the location of an explosion 2 years before. The average cobalt 60 in three samples of clam livers was about 1.5 microcuries per pound (0.003 microcurie per gram). The factor of concentration for cobalt in these animals may be several hundred thousand over the amount in the water because radiocobalt could not be detected in the surrounding water or in the sand of the reef. Traces of cobalt, of course, are essential for nutrition of all animals and are a constituent of vitamin B_{12}. Zinc 65 is concentrated by food fishes by a factor of several thousand over the amount in sea water. The highest concentration is found in the liver, spleen, and skin. The average amount found in these organs of a parrot fish and a snapper from the same lagoon as the high-cobalt clam was about 0.7 microcurie per pound (0.0014 microcurie per gram). A tuna from the open sea in the same general area had about twice as much zinc per unit weight

as these lagoon fishes. The amounts in the fish flesh were lower by a factor of 10 than those in the internal organs and the skin. Considerably more than half of the activity was radiocobalt in the clams and radiozinc in the fish. The fish contained about 10 times as much zinc as cobalt whereas the mollusks contained considerably more cobalt than zinc.

From the standpoint of the possible hazard to human beings who might eat these heavily contaminated clams or fish it should be remembered that the biological half life in human bodies is only about 10 days for cobalt and zinc, while half of the strontium 90 ingested remains for nearly 10 years. As a result, the maximum permissible concentrations for radiozinc and cobalt are about 100,000 times that for radiostrontium (for children, 6 x 10 μc Zn–65/gram and 1.8 x 10^{-3} μc Co–60/gram).

Although strontium 90 makes up about 5 percent of the activity of fission products at the end of 2 years, it was found in fairly low amounts in the organisms of the Marshall Islands lagoons. Principal fission products in these organisms, other than cobalt and zinc, were cerium, praesodynium, and ruthenium. This relatively low level of strontium 90 probably results from the rich calcium supply. The biological concentrations of certain chemical elements are shown in table 6. The effect of a rich calcium supply on strontium uptake is shown in tables 7 and 7a, where only the highly calcareous soils of the coral atolls compare with the condition in the sea.

16. Table 8 shows several of the important effects discussed in the foregoing. In a region of intense close-in fallout over the sea the Sr–90 is relatively unimportant in fish because of mixing and dilution with calcium and because of discrimination against strontium by fish. Zinc 65, on the other hand, can be far more important because of the low level of zinc in sea water and the concentration of zinc by marine organisms.

17. The marked differences in the concentration of various radioactive substances in different parts of marine organisms should be considered, for in the case of some marine organisms not only the flesh but the skin, viscera, and bones are eaten. Table 9 shows added information on the great variation of activity between tissues of marine organisms.

18. Insofar as marine plants and animals are concerned we must distinguish between pelagic organisms, which, although many of them are vertically migratory, can absorb fission products only from water in which they immediately move, and fixed animals and plants such as oysters, mussels, other shellfish, and kelp, which filter great quantities of water as it moves by them. Some insoluble or precipitated radioactivity tends to be concentrated on the bottom just as it is concentrated on the land surface. Thus the levels of radioactivity to which bottom-dwelling organisms are subjected may be somewhat higher than the pelagic organisms experience. In the lagoons of the Marshall Islands the fish living freely in the waters of the lagoons show beta activity less than that of the bottom-dwelling gastropods. The organisms living in the adjacent sea areas show a level similar to those of free-swimming fish in the lagoon.

Thus different problems may be associated with commercial fisheries that take benthic or bottom-dwelling organisms and the fisheries for pelagic creatures. In addition, many of the benthic fisheries are below the thermocline and subjected to the effect of deep rather than shallow contamination.

19. In considering the distribution of weapon-produced radioactivity between the upper and lower levels of the ocean, attention must be paid to the size and location of the weapons; for example, a deep underwater burst of a nominal weapon will leave approximately two-thirds of the radioactivity below the surface layers and only one-third in the surface layers.

20. In addition to radioactive fallout from the explosion of nuclear weapons, we must also consider the disposal of radioactive wastes at sea particularly in coastal shallow waters and the possible hazard arising from accidents; for example, the sinking of nuclear-powered ships and the accidents to reactors located near the sea and using ocean cooling waters.

If and when an appreciable part of the world's merchant fleet is powered by nuclear reactors, serious hazards may arise in confined waters from collisions in which the reactor is damaged and the fuel elements with their contained fission products are lost in the water. Suppose for example that a 50,000-kilowatt reactor (probably fairly typical for a large fast freighter) has been in service without refueling for 1 year on a ship that has spent half its time underway. Approximately 10 kilograms of fissionable material will have been used up and the total amount of fission products will be approximately 10^7

curies. If, owing to a collision, the reactor is lost in a harbor, say 8 miles long by 3 miles wide by 50 feet depth, and the fission products become uniformly distributed, the water in the harbor would contain 10^{-2} curies per cubic meter giving an almost constant radiation dose of about .5 r per day on the surface. Dock pilings, ship bottoms, and other structures covered with fouling organisms would accumulate a much higher level of radioactivity, and, of course, local concentration in the water may be extremely high.

21. Food habits of different nations must be taken into account in evaluating the hazards to human beings from fallout over the oceans. This is particularly true in the case of the Japanese, who obtain about one-third of their calcium from marine fisheries. Table 10 shows the sources of calcium in the Japanese diet.

To accomodate these differences we must investigate the differences between the terrestrial and marine uptake problems for specific isotopes. For example, coming specifically to the strontium 90 problem we have made a comparison between the strontium 90 that will be obtained from land-derived and ocean-derived foods in table 7.

Three factors enter into this: (1) The much higher concentration of calcium in soils than in sea water, (2) a dissemination of strontium 90 from fallout in a much greater volume of water in the ocean than soil on land, and (3) the different amount of discrimination against strontium in fish than, for example, in milk cows.

22. Although maximum permissible concentration has been established for most radioactive substances, recent evidence indicates that much smaller amounts of radioactivities do produce physiological effects, for example leukemia.

23. Introduction of radioactive substances in the ocean has beneficial as well as harmful effects in so far as it enables us to use tracer techniques in the study of the movement of the water and the life cycles and metabolism of marine organisms. As an example figure 1 indicates the intrusion of a clean water mass along the level of high stability and the persistence of deep activity around Bikini Atoll 2 years after an event.

TABLE 1.—*Apparent effect of runoff on activity of nearshore ocean water—Samples of suspended sediment*[1]

Date of collection 1957	Preceding weather	Activity[2]		
		Zr, Nb	Ru, Rh	K^{40}
April 12-22	Calm, dry	5,000	1,200	900
April 22-May 5	do	2,000	900	900
May 5-16	Calm, rain	11,000	4,000	900
May 16-20	Heavy swell, intense rain	22,000	2,300	900

[1] Collected by filtering water from about 300 meters offshore at La Jolla where the sediment concentration is 10-30 p. p. m. of the seawater (from unpublished data T. R. Folsom).

NOTE.—The data in this table were principally gathered from Vinogradov (1953), unpublished results of E. Goldberg and Laevastu and Thompson (1956).

TABLE 7.—*Factors of Sr-90/Ca concentration for conditions of equal fallout*

Material	(Sr-90/Ca, soil=1)	Present concentration [1] curies/grm Ca
Unplowed soil (Wisconsin)	1	3×10^{-11}
Alfalfa	0.75	
Animal bone	0.25	
Milk	0.10	3×10^{-12}
Seawater	0.005	1.5×10^{-13}
Fish flesh (pelagic)	0.0015	
Whole fish (pelagic)	0.0005	1.5×10^{-14}
Plowed soil (2 feet)		
All Ca from fertilizer (.02 gm/cm²)	1	
All Ca natural	0.1	
Highly calcareous soil (Marshalls)	0.003	

[1] For 25 MT worldwide fallout.

TABLE 7-A.—*Radioactivity levels in nearby fallout area as of February 1955*

Item	Median total B- μc/gm	Median Sr90 μc/gm	Item	Median total B- μc/gm	Median Sr90 μc/gm
Lagoon:			Islands—Continued		
Large fish	4×10^{-5}	9×10^{-8}	Ferns	1×10^{-4}	
Small fish	8×10^{-5}		Coconuts	2×10^{-5}	1×10^{-7}
Crabs and clams	5×10^{-4}		Arrowroot	6×10^{-5}	1×10^{-7}
Snails	2×10^{-3}	1×10^{-6}	Pandanus	7×10^{-5}	6×10^{-7}
Coral	8×10^{-5}	4×10^{-7}	Papaya	6×10^{-5}	8×10^{-8}
Water	2.3×10^{-6}	9×10^{-8}	Breadfruit	6×10^{-6}	
Plankton	9×10^{-5}	9×10^{-8}	Morinda fruit	7×10^{-5}	1×10^{-6}
Islands:			Ocean:		
Rats	4.5×10^{-4}		Jellyfish	4×10^{-4}	ND
Fresh water algae	7×10^{-3}	4×10^{-6}	Fish	3×10^{-5}	ND
Fresh water	8×10^{-7}	8×10^{-8}	Plankton	6×10^{-5}	ND
1st inch soil	5×10^{-3}	2×10^{-5}	Water	9×10^{-7}	ND
Rooster	6×10^{-4}				

TABLE 8.—*Sr-90 in nearby fallout (assuming no fractionation from fission products)*

	curies/cm.²	Sea water, curies/gram Ca	Whole fish, μ curies/gram flesh	Proportion MPD [1]
Maximum	1.1×10^{-7}	2.7×10^{-8}	6.6×10^{-7}	8.0
Mean	6.0×10^{-9}	1.5×10^{-9}	3.8×10^{-8}	0.5
Minimum	2.0×10^{-12}	5.0×10^{-13}	1.2×10^{-11}	0.00015

	curies/cm.²	Land, Wisconsin, curies/gram Ca	Milk, μ curies/gram	Proportion MPD [1]
Maximum	1.1×10^{-7}	5.4×10^{-6}	6.5×10^{-4}	8,000
Mean	6.0×10^{-9}	3.0×10^{-7}	3.6×10^{-5}	500
Minimum	2.0×10^{-12}	1.0×10^{-10}	1.2×10^{-8}	0.15

Zn-65 in same fallout (assuming Zn-65 induced in equal atom yield to Sr-90)

	curies/cm²	curies/gram Zn	Fish flesh		Fish liver, proportion MPD [1]
			μ c/gram	Proportion MPD [1]	
Maximum	5×10^{-6}	1.0×10^{-1}	1.0	800	8,000
Mean	2.7×10^{-7}	5.4×10^{-3}	5.4×10^{-2}	18	180
Minimum	9.0×10^{-11}	1.8×10^{-6}	1.8×10^{-5}	0.006	0.06

[1] For children.

TABLE 9.—*Variation of radioactivity in different parts of a single fish*[1]

	Gama activity
Body part	([2])
Liver	1,060
Stomach and contents	320
Vertebrae	60
Flesh	40
Spleen	2,200
Gall bladder	440
Kidney	100
Tail fin	200
Scales	60

[1] Snapper collected in Marshall Island lagoon April 1956, and counted immediately.
[2] d/m/gm of wet weight.

TABLE 10.—*Average per capita daily intake of calcium in Japan from Hiyama, Y; maximum permissible concentration of Sr-90 in food and its environment, Records of Oceanographic Work in Japan, vol. 3, 1956*

Kind of food	Ca (mg.)	Sr/Ca by weight
Marine fish	120	1/100
Freshwater fish	5	1/100
Rice and cereals	150	1/1,000
Vegetable, milk, and others	100	1/1,000
Total	375	

Principal isotopes from slow neutron fission of 1 kilogram U-235

Isotope	Percent	Activity in curies	Isotope	Percent	Activity in curies
1 day, 3.22×10^8 curies:			20 days, 9.8×10^6 curies—Continued

Dr. REVELLE. I would like to begin, Mr. Chairman, by making some generalities about the ocean. These are all platitudes, but we have to keep them in mind in considering the problem of radioactivity in the ocean. In the first place, the ocean is very large and very deep. It covers about 71 percent of the earth's surface, and its average depth is 4,200 meters or about 14,000 feet. Second, it is a highly concentrated salt solution. It contains almost all of the known chemical elements, many of them, however, in very small quantities.

Third, the ocean is stratified, that is, there is subsurface mixed layer on the average somewhat less than 300 feet thick, and below this is a series of layers of increasing density which have relatively little communication with each other, except in high latitudes and along the shores. The surface mixed layer, the top 300 feet, is of principal interest to human beings because it is in this layer that most of the organisms, most of the marine plants and animals that constitute the ocean harvest, live at least most of the time. There is very rapid mixing within the top layer, and very slow mixing between the upper layer and the depth.

Fourth, there is a very low level of natural radioactivity in the ocean. The natural radioactive substances such as potassium 40 are present only to the extent of one one-hundredth—the total of all natural radioactive substances in the ocean is only about one one-hundredth of that on land in terms of their radioactivity.

As a result both sailors and fish have a much lower level of exposure to natural radiation than any other creatures living on the earth.

Representative HOLIFIELD. I assume that is true except on the *Lucky Dragon.*

Dr. REVELLE. That is right. I said natural radioactivity.

Fifth, most fallout ends up in the ocean. This is true for 3 reasons. In the first place, a large part of the tests of nuclear weapons have been conducted over the ocean—those tests conducted by the United States and the British. The close-in fallout nearly all falls over the sea. Because the ocean covers 71 percent of the earth's surface, a very

large part, up to 71 percent but probably somewhat less, of the stratospheric fallout falls in the ocean. As far as the distant so-called tropospheric fallout is concerned, the portion is less than 71 percent, because of the higher percentage of land in the Northern Hemisphere, but still probably about 50 percent.

The rapid mixing to somewhere between 50 and 100 meters of the ocean means that fallout falling on the sea surface rapidly is diluted down to this depth. In the trade-wind region it takes about 30 hours for very small particles to be thoroughly mixed in the top hundred meters. This gives great protection to ships and to anybody on the surface of the sea, provided the fallout does not actually end up on him or his ship. The fallout ending up on the surface of the ocean represents a hazard from external radiation of a fifth to a hundredth of the corresponding fallout on the land. During the first half hour after fallout the factor of protection is about five; that is, the amount of the radiation is about one-fifth or about 20 percent of that from a land surface. After the first half hour the amount of radiation received is only about one hundredth.

The waters of the ocean move, but they move very sluggishly. The average speed of the surface currents is about 0.5 of a mile per hour to 1 mile per hour. That is somewhere between 12 and 24 miles per day. The mixing between the upper and lower layers probably takes something of the order of 200 to 500 years to occur. This is true except in areas of upwelling along the shores of the ocean where water of intermediate depths comes up to the surface in considerably greater speeds but still quite slowly—only 1 or 2 meters a day.

Representative HOLIFIELD. Are there areas in the deepest part of the ocean where the water remains permanently there and does not come up to the surface as far as you know?

Dr. REVELLE. Not as far as we know. But the best chance for finding deep water that has been there for perhaps as much as 1,000 years is in some parts of the Pacific Ocean. So far we have not really carried out enough investigations to know how long it does stay down.

Representative HOLIFIELD. No doubt you realize the reason for my question is the problem of disposal of radioactive wastes. Of course, that will be testified to later. We have some testimony on the disposal of radioactive wastes, but I thought I would take this opportunity in view of the fact that you are speaking on the ocean phenomena to ask you that question.

Dr. REVELLE. As a matter of fact, I have given a great deal of thought to this. I am the chairman of the National Academy of Sciences' Committee on the Effects of Radiation in Oceanography and Fisheries, and this is one of the questions that we have been very much concerned with. I believe that certainly some protection can be gained even from fairly long-lived fission products by putting them into the deep sea. But the question of how much protection depends on a whole series of unknowns, and one of these certainly is the rate at which the deep water moves up to the surface. We think that in the Pacific it may be perhaps more than 500 years, although there is a very large factor of uncertainty.

More important probably than the rate at which the deep and surface waters mix is the fact that the deep waters themselves mix, and become fairly well homogenized over very large volumes so that the concentration of radioactivity might be quite low. The thing

which bothers us, as I will point out in a minute, is that the marine organisms concentrate radioactivity by a very large factor.

I might also point out that the marine organisms, unlike the waters, move fairly rapidly. Many of them conduct a vertical migration between day and night over a depth of 1,000 or 2,000 feet. They move up to the surface in the night and down to a depth of several hundred fathoms during the day. Many of the fish we are interested in, such as tuna, marlin, sailfish, bonito, skipjack, and salmon, migrate over very large horizontal distances. This is also true of the marine mammals such as the whales.

Representative HOLIFIELD. Do they feed on any of the marine life that moves vertically up and down?

Dr. REVELLE. Yes, sir, they do indeed; particularly the whalebone whales, and the tunas feed almost exclusively on these smaller organisms which do migrate over depths that I have mentioned.

Representative HOLIFIELD. What are the natures of some of the small organisms? You are not referring to plankton?

Dr. REVELLE. I am referring to zooplankton and other invertebrates which swim, such as the squid. In tropical regions of the Pacific very large tuna are obtained by the Japanese at considerable depths below the surface during the daytime and presumably the big tunas are down there, because that is where their food supply is, although this is not very well known, either. I do not want you to get me wrong. We really know very little about the ocean. Everything I say is subject to a good deal of uncertainty.

Representaitve HOLIFIELD. That is spoken like a true scientist. I think any scienist who testifies before us disclaims any knowledge whatever of the subject upon which he is testifying. We take that as modesty and we would rather have you that way than the other way.

Dr. REVELLE. As a matter of fact, in my case it is not modesty. It is just a simple statement of fact. Oceanographers are masters of not knowing very much about what they are doing. One of the things that is very often said, and I think with complete justification, is that we know less about the bottom of the ocean than we do about the surface of the moon.

Although the ocean has almost every substance in it, many of these substances, as I pointed out a minute ago, are present in very low concentration. Hence in order to live marine organisms have to concentrate the substances they need for their growth from sea water. Often they concentrate such substances—these trace substances—by factors of many thousand times. This necessity for concentrating trace substances from sea water means that the marine organisms are especially adapted for doing this job, and it means they will concentrate other substances present in small concentrations, such as artifically radioactive substances originating from fallout, or in other ways also by factors of many hundreds to many thousand of times.

What is the significance of these generalities? I have stated nearly everything I can in my prepared statement, but perhaps we might summarize some aspects of this problem of the significance. Coming first to the close-in fallout, even several months after a major weapons test there is a relatively high level of fallout within 500 to 1,000 miles of the test site for a period of at least a few months. This depends, in the case of the Marshall Islands area, on the sluggish

nature of the motion of the water. Here I have shown on this chart the surface currents in the neighborhood of Bikini Atoll. Here is Bikini. Here is Eniwetok. Kwajalein gives you some idea of the scale of the chart. The green lines show the surface current and the red lines currents at a depth of about 1,000 feet.

We see that the surface currents are somewhat disturbed by the existence of the atolls. But in general we have a motion from east to west of the order of half a mile per hour, or about 12 miles per day. At a depth of about a thousand feet, there is a very much more obvious effect of the existence of the islands. We see a great eddy in the neighborhood of Bikini Atoll. The water, instead of moving past the atoll, tends to stay in this area right around the atoll for a very considerable length of time.

As a result of this difference in the circulation near the surface and at depth, a graph in my statement shows that in fact after 2 years the concentration of radioactive substances in the neighborhood of Bikini is much higher at depth than at the surface by a factor of 2 or 3. It is quite low, however, at all depths. That is 2 years after a test.

Representative HOLIFIELD. Is that strong enough to affect the edibility of the fish in that area?

Dr. REVELLE. Yes, sir, it certainly is, as I will show you in just a few minutes. I simply want to point out here the relatively sluggish motion of the currents, which means that the fallout tends to stay in this general area, but is diffused laterally and as I pointed out, vertically in the top 100 meters.

I am sorry the next chart is on such a small scale, but these will be left with you. This small scale has the great advantage that it shows how big the ocean is. This is the water hemisphere covering just about half the earth—the Pacific Ocean. In this area in here this is Bikini, here is Japan, the Philippines, New Guinea, Australia, United States, and South America. This area of 1,000 miles around Bikini was carefully investigated by Japanese oceanographers and biologists 4 months after the Castle test. They got figures like this in the water: 23,000, 90,000, 79,000, 26,000 disintegrations per minute per liter of sea water. The values that we are talking about here are values of the order of one one-hundredth to three one-hundredths of a microcurie per liter of water 4 months after a test. The distribution was quite spotty as we go along this time. (See folding chart, p. 551.)

I will read some numbers—5,100, 90,000, 14,000, 16,000, 23,800, and 16,500. This is at a distance of about 300 miles.

Representative HOLIFIELD. Is that measurement of quantities of sea water?

Dr. REVELLE. Those are disintegrations per minute of radioactive material.

Representative HOLIFIELD. In a certain amount of sea water.

Dr. REVELLE. In a quart of sea water. This is about 300 miles west of Bikini Atoll. When we go a thousand miles west of Bikini, we get much smaller values. The biggest one here is about 4,500 disintegrations per minute per liter.

Representative HOLIFIELD. What is the natural disintegration per minute per liter?

Dr. REVELLE. In the water itself, due to the natural radioactivity, if we are talking about gamma radiation, it is about 50 disintegrations

per minute per liter. For gamma plus beta about 10 times this amount, or about 500; 70, I guess, is a better figure than 50. You can see over a distance of several hundred miles, the amount of radioactivity in the water was as much as a hundred times greater than the natural radioactivity. The radioactivity in fish caught in this area was very widely variable. One fish caught here about 100 miles west of Bikini had between three and four hundredths of a microcurie per gram in its liver. In other words, about 10 microcuries per pound of fish liver.

Chairman DURHAM. That is a much more rapid disintegration in sea water than it is on land.

Dr. REVELLE. It is a more rapid disperson because of the mixing, as I pointed out, down to a hundred meters, and because of the horizontal spreading of the water.

Chairman DURHAM. It does not have any effect on the half life.

Dr. REVELLE. It does not have any effect on the half life, except that you do get some separation due primarily to the fact that some materials are larger than others, and settle to great depths.

Thirteen months after the test, the situation is shown by the next chart. This shows the result of a cruise conducted by the Atomic Energy Commission and the Office of Naval Research in which oceanographic work was done by Dr. Wooster and others of my institution, and the radioactivity measurements were made by the New York operations office of the AEC under the direction of Dr. Harley. By this time, 13 months later, the radioactivity had moved all the way to Japan, but it was present in very much smaller concentrations. The maximum was off the Philippines, where about 5 times background was obtained. Mostly the values were only a couple of times background. (See p. 551.)

Representative HOLIFIELD. Would that be sufficient strength to affect the edibility of the fish in that area?

Dr. REVELLE. I am not sure it would affect the edibility, but it certainly affects the radioactivity of the fish.

Representative HOLIFIELD. Would the measurement in the areas where fishing is done for food be detrimental to the human body?

Dr. REVELLE. It is my opinion that they probably were not, this far away. I will come to some other considerations on this subject in just a minute. Actually I would like, if possible, to refer you to one of the tables here, if I may. I am not sure I have this figure quite straight there. I guess we have not got any table from that far away in this particular operation. I should refer you to the report which is called Operation Troll. It is given among my references on page 5, United States Atomic Energy Commission, 1956. That is page 5 of the references. That publication gives the values of the radioactivity. I am sorry I don't remember them. I simply wanted to use this chart to point out how the radioactivity is spread over the course of 13 months after the test, and how spotty it is, the maximum being over here [indicating on the chart].

Representative HOLIFIELD. What are some of those figures?

Dr. REVELLE. These are disintegrations per minute per liter of water in excess of the natural background. The highest value was 210 off the Philippines. Here, south of Japan, it was 192 distinegrations per minute per liter of water. In the plankton the disintegrations are per minute per gram. The highest value was again off the

Philippines: 118 disintegrations per minute per gram. The highest value, I am sorry, was between the Philippines and Japan. That is 137.

Representative HOLIFIELD. That is in the plankton, you say?

Dr. REVELLE. Two thousand disintegrations per minute would be a thousandth of a microcurie. So this is about one ten-thousandth of a microcurie per gram of plankton.

Representative HOLIFIELD. Is it not true that as you go up from the plankton to the fish that you get an unusual multiplication of that?

Dr. REVELLE. It depends entirely on the substance we are talking about.

Representative HOLIFIELD. If we are talking about plankton that is consumed by the lower forms of marine life, and there is a very marked increase in concentration—in other words, they collect it and maintain that out of the plankton—until its cumulative effect in the higher form of marine life is much more marked. Is that not true?

Dr. REVELLE. I don't think that is so, sir. The actual factors of concentration are shown in table 6 of my statement. You will see that the vertebrates, which in the sea are primarily fish, do concentrate some substances to a much higher degree than the plankton which they eat, and this is particularly true of zinc. In the case of strontium, the fish discriminate against strontium by about a factor of three. In the case of iron again there is a very considerable discrimination in the vertebrates as opposed to the invertebrates. On the other hand, the fish do concentrate phosphorous by a factor of 2 million whereas the invertebrates never go above 10,000. So it is not possible to make any generalization. We have to investigate every element—not every isotope—independently. This depends on how the organism absorbs the material, whether it comes to it by simply physical absorption or in its food supply and whether he needs the substance for growth or for his vital processes.

These, I should emphasize, are the best estimates that a group of us on the National Academy Committee could make. I still would not be willing to place a bet at any odds on any one of those figures.

The next chart shows the distribution of fish catches that had more than 100 counts per minute when assayed by the Japanese within the first 6 or 7 months after the 1954 test. You can see that unlike the water and the plankton, which behaves just like water, the migratory fish extend over a very much wider area. On the other hand, most of these fish had a relatively small amount of radioactivity in them. As I remember, the Japanese monitored 78,000 tons of fish. Only 385 tons were found to have more than 100 counts per minute with the type of equipment they used. (Portion of chart, p. 552.)

Chairman DURHAM. What do you mean by counts?

Dr. REVELLE. Just the number of counts on the Geiger tube.

Representative HOLIFIELD. That would not make the fish inedible?

Dr. REVELLE. This is a matter of opinion. The Japanese discarded all these fish.

Representative HOLIFIELD. Then it was inedible as far as they were concerned.

Dr. REVELLE. If we look at the distribution of radioactivity in the fish, remember, only one-half of 1 percent of the fish were found to be radioactive, to give you figures—something like 385 tons were discarded out of 78,000 tons. Only about 3 or 4 tons, about 1 percent of

the discarded fish—0.8 of a percent to be exact—had more than 5,000 counts per minute; 65 percent had a count of less than 100 counts per minute.

Representative HOLIFIELD. Could you tell us if the high counts occurred at specific times after the test? That is, did it show a pattern in relation to any specific test or was it fish that were obtained without direct relation to time.

Dr. REVELLE. These were fish that were obtained, I think, within the first 7 or 8 months after the first Castle series of tests. In this time period there did not seem to be any relationship between the count and the time. This is partly due to the fact that we have a rather inadequate sample.

Representative HOLIFIELD. You say a rather inadequate or an adequate sample?

Dr. REVELLE. A rather inadequate sample. I just do not know. I will point out, however, that nobody could sample the ocean better than the Japanese. Their fishing is conducted over almost the entire ocean and very intensively, in contrast to the United States, where about 11 pounds of fish per person are eaten per year, and the Japanese eat about 80 pounds of fish per person per year.

Representative HOLIFIELD. This certainly explains to some extent part of their concern, because they are dependent upon the sea for a substantial part of their diet.

Dr. REVELLE. Yes. As I will try to show in a few minutes, this has itself both good and bad aspects from the point of view of radioactivity.

So much for the charts. A great deal has been said about strontium 90 and the dangers from it because of its being a long-lived fission product which is a bone seeker. One thing that can be said from this point of view about the ocean is that strontium 90 in the ocean represents a considerably smaller hazard than strontium 90 on most soils.

Chairman DURHAM. Has there been the same general increase since 1952 as has been on the land?

Dr. REVELLE. Remember what I said to begin with.

Chairman DURHAM. That is why I asked the question.

Dr. REVELLE. At least three-quarters of the strontium falls into the ocean. However, it is present in quite low concentrations in the ocean compared to the concentration on the land.

Chairman DURHAM. But there has been an increase.

Dr. REVELLE. There certainly has been an increase in principle. There are not enough analyses for us to tell you the figures of what this increase is. It should be fairly clear cut from an a priori point of view. We know it will mostly stay in the surface layers and mostly spread throughout the surface layers.

Representative HOLIFIELD. Because there is more depth and area in the ocean there is more chance for diffusion of fallout than the land, which must necessarily concentrate it in the first few inches of soil.

Dr. REVELLE. That is absolutely correct. Table 7 of my statement shows this quantitatively. If we compare the soil that Dr. Libby is always talking about, the Wisconsin soil—simply because his group on the Sunshine project has made a lot of measurements there—with other substances, you will see that the strontium-to-calcium ratio, if

we take it as one in the Wisconsin soil, and one-tenth in milk, in sea water will be only 0.005. In fish flesh, because of the fact that there is some discrimination against strontium in fish, it will be only 0.0015. In whole fish, including the bones, we have a strontium-calcium ratio only five ten-thousandths of that which we would find in the Wisconsin soil, and only five one-thousandths of what we would find in milk. It is only the very highly calcareous soils of the Marshall Islands region which result in little strontium in the food grown on them. It is for this reason that the Japanese eating a lot of fish and obtaining about a third of their calcium from fish, means that they are subjected in terms of food intake to very much less strontium 90 hazard than the people of Wisconsin.

Representative HOLIFIELD. I think that is a very important statement, Doctor, because if that statement can be sustained, it disposes of what is, I believe, a common belief that there is a great buildup in the Japanese people because of their diet of fish.

Dr. REVELLE. I think the facts are, sir, as I attempted to point out, that the reverse is probably true from the standpoint of strontium alone. The fact that their calcium intake is in large part from fish means that they will suffer less hazard from strontium.

Chairman DURHAM. What part of the fish does the strontium assimilate itself in mostly?

Dr. REVELLE. Most of it goes to the bone. However, the strontium-calcium ratio in the flesh is higher than in the bone. You often hear it said that strontium in the fish bone does not represent a hazard. I don't think this is true. The Japanese, and in fact all of us, eat fish bones all the time, not by accident, but by design. Whenever we eat a sardine or anchovy or small herring or many little fish, we eat them bones and all. We eat the skin which also very often tends to concentrate these radioactive substances.

Representative HOLIFIELD. Let me ask you a question which I certainly do not understand thoroughly myself. It has been called to my attention that the Japanese people are concerned about radioactive iodine 131. Could you shed any light upon that particular point?

Dr. REVELLE. No, I cannot. I would think that this is not a problem they would face with their fish catch, although I may be wrong. It has such a short life I would think they are primarily concerned there with fallout—the tropospheric fallout—reaching them either by the winds from the Marshall Islands or from Russia.

Representative HOLIFIELD. This element would not be collected by either the fish or by any vegetation which is grown in the sea. If I remember, they do use some of the kelp, do they not, in the sea as an element of diet in Japan?

Dr. REVELLE. That is correct. It is certainly concentrated by marine organisms. If you look at table 6, you will see that algae concentrate iodine by a factor of 10,000 and vertebrates by a factor of about 1,500.

Representative HOLIFIELD. Then it would be in some sort of marine vegetation rather than fish if it is in existence?

Dr. REVELLE. That is right. However, the Japanese eat a lot of marine plants and algae. Everything you eat in Japan is wrapped in seaweed practically. I don't have any opinions on this subject.

Representative HOLIFIELD. We will explore that later when we get to the medical part of our testimony.

Dr. REVELLE. We have not considered that because it has such a short half life.

Continuing with the strontium for just a minute, it is clear that only that in such calcareous soil as the Marshalls is the hazard from strontium 90 less than it is in marine animal foods. This is demonstrated in table 7–A, where we have listed the concentrations of radioactivity found in marine animals and in the water, in land animals and in the soil, and in the open ocean as well as in the lagoons from the Marshall Islands area as of February 1955. You will see that although the lagoon water had 2.3 times 10 to the minus 6 microcuries per gram, while the soil had 5 times 10 to the minus 3, a factor of 2,000 greater for the same amount of material the amount of strontium——

Representative HOLIFIELD. Which one are you referring to now?

Dr. REVELLE. Just look in general terms there. Just take a quick look at all of the figures on table 7–A. First look at the water. Notice how much more radioactivity there is in the soil than in the lagoon water, and more in the lagoon water than in the open ocean.

Second, notice that total radioactivity in the marine animals is just about the same as the total radioactivity in the land animals and the land plants. These numbers obviously cover quite a range. One gets the impression that the radioactivity in the marine animals is about the same as it is in the land animals, not only in the lagoon, but also in the open ocean. The marine animals have concentrated the radioactivity by a factor of as much as a thousand over that in the water, whereas the land animals in general have not concentrated the radioactivity, but have less radioactivity than the soil in which they grow. So we have just the reverse effect between the marine animals and the land animals as opposed to the water and the soil.

On the other hand, notice the strontium values for the most part in the marine organisms are no greater—they are about the same—as the strontium values in the land animals. The marine and land animals have about the same strontium even though the marine animals have concentrated radioactivity relative to the water, whereas the land animals have lost radioactivity relative to the soil. In a soil with less calcium than the Marshall Islands soils, the land would have relatively much more radiostrontium. This is because of this protection that marine animals have from strontium because of the fact that the strontium-calcium ratio is different between the ocean and ordinary soils.

Representative HOLIFIELD. There is more calcium available to them?

Dr. REVELLE. That is right.

Chairman DURHAM. Looking at the water, Doctor, is the water on the island used for consumption? I notice your table runs about the same with fresh water.

Dr. REVELLE. I don't know, sir.

Chairman DURHAM. The ocean water runs 9 to 10.

Dr. REVELLE. I am sorry I did not understand your question.

Chairman DURHAM. I asked the question did they use the water on the island because of the fact that it carries just about as much strontium as the salt water does.

Dr. REVELLE. Yes, that is right. I don't know whether this water was used.

Chairman DURHAM. I should imagine they have to drink water.

Dr. REVELLE. Yes. These were not inhabited islands at the time of the measurements. I am afraid I may have confused this, but perhaps we can straighten it out in the record. The fact is that the strontium is about the same with these very, very calcareous soils, and with soils that are less calcareous we have more concentration in the land plants and animals than in the marine animals.

Even with the maximum amount of fallout observed in the Marshall Islands area, as shown in table 8—remember that this is very spotty—nearby fallout very shortly after the test, the fish living in that water and keeping the concentration at the maximum would still have only eight times the maximum permissible dose in terms of microcuries per gram or microcuries per milliliter. Whereas with similar fallout on land, milk would contain 8,000 times the maximum permissible dose.

This is just another way of emphasizing the same thing, the great advantage that the people who eat fish have over the people who drink milk and get their calcium that way.

Representative HOLIFIELD. In order to clear up this in order that no one may say that this ratio of contamination exists in Wisconsin, this would be assuming that we had the same kind of test in Wisconsin that we had in the Marshall Islands.

Dr. REVELLE. Exactly; yes.

Representative HOLIFIELD. That is a completely hypothetical assumption and therefore nothing for anyone to take alarm at.

Dr. REVELLE. I should hope not, except that they ought to eat more fish.

In contrast to the strontium problem, there are two substances produced by the large weapons tests which are not fission products. One of them is cobalt 60, and the other is zinc 65. Zinc and cobalt are a necessity for growth. Surprisingly enough, they are very highly concentrated by marine organisms, but not by the same organisms. You will notice in my statement on page 6, amounts as high as one-third of a microcurie of cobalt 60 were found in the liver of an 8-inch clam in a location off the Marshall Islands, about 80 miles from the location of an explosion 2 years before. The average cobalt 60 in 3 samples of clam livers was about 1½ microcuries per pound. The factor of concentration of cobalt in these animals may be several hundred thousand over the amount in water because radiocobalt could not be detected in the surrounding water or in the sand of the reef. In other words, these clams and mollusks in general are very much better chemists than people are. They are able to make separations very much more effectively than we are able to do by any of the presently available techniques.

It should be remembered that traces of cobalt are an essential constituent of human life, and are a part of vitamin B-12. It is one of the constituents. This concentration of cobalt took place in the clams.

Zinc 65 on the other hand was concentrated by the fish and just about to the same extent that the cobalt was in the clams. The highest concentration was found in the internal organs and in the skin. The average amounts in these organs of a parrot fish and a snapper were about 0.7 of a microcurie per pound, or about 0.0014 microcurie per gram.

Tuna from the open sea had about twice as much zinc per unit weight as these lagoon fish. The amounts in the fish flesh were lower by a factor of 10 than those in the internal organs and the skin. Considerably more than half of the entire radioactivity in the clams was radiocobalt and in the fish was radiozinc. The concentration of radiocobalt was 10 times higher in the clam and of radiozinc 10 times higher in the fish. Before we get alarmed about these figures, because of the biological half life of both cobalt and zinc being relatively short compared to the biological half life of strontium 90, the maximum permissible concentrations for radiozinc and radiocabalt are about 100,000 times those for strontium. For example, these average values about 80 miles from the test site 2 years later of about 0.0015 microcurie per gram are about a fourth of the average permissible dose for zinc. The average concentration of 0.003 microcurie of cobalt was about twice the maximum permissible dose for cobalt.

I would like to say two other things. The first one is that marine organisms live in different radiological domains, even with respect to artificial radioactivity. Some of the radioactivity settles through the water onto the bottom or can settle through the water onto the bottom, and bottom living organisms just like organisms on land therefore tend to be subject to a higher dose than organisms swimming freely in the water. There are such things as clams and other marine mollusks which are eaten by many people, including, I hope, by most people in this room. Also, kelp and seaweed. Kelp is very widely harvested and used in this country. Every quart of ice cream you eat has some algae and kelp in it. These bottom living organisms are attached to the bottom through which and across which the water flows, and tend to live in a different radioactive regime than the organisms that swim freely in the water.

Finally, I should point out that there are many ways both actual and potential in which artificial radioactivity can get into the ocean besides the fallout from nuclear tests. One of the ones that must certainly be kept in mind is the possibility of an accident to a nuclear powered ship. Suppose, for example, that a reactor is damaged and its fuel elements with their contained fission products are lost in the waters of an average size or somewhat small size harbor in the United States, if this is a 50,000 kilowatt reactor, which does not seem to be exceptionally large, and has been going for a year, there will be approximately 10 kilograms of fission products, making up about 10 to the seventh curies. In a harbor 8 miles long by 3 miles wide, 50 feet in depth, if the fission products become uniformly distributed, the water would contain about 10 to the minus 2 curies per cubic meter, giving almost a constant radiation dose of about 0.5 of a roentgen per day on the surface. So there is a real hazard from a nuclear reactor which is damaged—a shipborne nuclear reactor in a harbor.

Representative HOLIFIELD. Of course, the Congress has authorized, as you know, a merchant marine ship for a large reactor. There has been 1 carrier and I believe there are 2 or 3 others. There are several submarines already in existence. As you point out, if by the very nature of war if these were destroyed or sunk or the reactors were disrupted by torpedoes, you would have this element of contamination, wouldn't you?

Dr. REVELLE. I am thinking of peacetime uses of atomic energy here. Just the very attractive prospect of powering a merchant fleet

with nuclear power. The number of collisons between merchant ships is surprisingly large. I think some attention should certainly be paid to this problem, and I believe the Atomic Energy Commission and the Maritime Commission are thinking quite seriously about it.

Representative HOLIFIELD. I hope the care is being given to it that should be given to it.

Dr. REVELLE. The other ways in which fission products and other artifically radioactive substances can get into the ocean are by the disposal of atomic waste. This question is a very complicated one, as you undoubtedly know, who have been ont his committee for several years. My own opinion is that although in this country it may be possible to dispose of the waste from the nuclear power industry in several ways, that this may not be so easy in countries like England, Italy, and Japan, which have a very dense population, have not got many holes in the ground, and are completely surrounded by the ocean. Of course, as we know, most countries which are now operating reactors are in fact disposing of low level wastes into the coastal waters. I urge at every opportunity in public that this matter should be very carefully controlled. I am glad to see the United Nations Committee on Biological Effects of Radiation has now taken the same point of view.

Representative HOLIFIELD. I think that it accents the importance of these hearings, too, to bring a realization to the people that we are dealing with a very serious element here, and the disturbance which it can make to nature if it is not controlled properly.

Dr. REVELLE. On the other hand, a very valuable one if it is controlled. The potentialities are tremendous.

Chairman DURHAM. I assume from your statement, then, Doctor, that you would not recommend it as a burial ground?

Dr. REVELLE. What was that, sir?

Chairman DURHAM. That you would not recommend the ocean as a burial ground for fission products?

Dr. REVELLE. I think that I would not either recommend it or not recommend it. I think the probabilities are that the ocean can be used for this purpose, but we really need to know a good deal more than we know now about the concentration of different substances by different organisms and in different parts of organisms. We need to know a lot more than we now know about the circulation and particularly the vertical movement of the ocean waters. We need to know a lot about the potentialities of transport of radioactive substances by organisms moving from one layer to the other. We also need to know something even more fundamental and much more difficult to understand, and that is the nature of the mixing process in the ocean, and particularly the exchange between the bottom muds and the waters as well as the rates and character of dispersion in the water itself. The problem here is that this seems to be quite spotty. You get high concentrations and low concentrations.

Representative HOLIFIELD. Would you say that this is an area where a great deal of research is needed?

Dr. REVELLE. I think that research is needed, but I naturally would, being an oceanographer.

Representative HOLIFIELD. Could you tell me how much research is actually being done? Let us put it that way.

Dr. REVELLE. It is very hard to separate one kind of marine research from another.

Representative HOLIFIELD. How much is directed toward the development of information on this so-called vertical movement from the lower muds up to the surface?

Dr. REVELLE. Actually very little indeed on this problem. The Woods Hole Oceanographic Institution, the Lamont Geological Observatory, the University of Washington, Texas A. and M., the Chesapeake Bay Institute, the Scripps Institution, the Japanese are all concerned with the problem, but not as yet with the level of effort that seems to be highly desirable.

Representative HOLIFIELD. Could you give us an estimate as to the number of scientists that are working on these projects and whether these projects are being financed by the grants from AEC or whether they are operating on other types of grants?

Dr. REVELLE. I am not sure that I can give you the exact figures, but my guess would be that the AEC is spending in these institutions that I listed something of the order of $150,000 a year. The Office of Naval Research and other parts of the Department of Defense are spending in related projects perhaps twice or three times this amount. The relationships are often not very close. This work that I have been talking about today, for example, has been supported by the Department of Defense and the AEC partly. As far as the Scripps Institution is concerned, it is supported more continuously by the Department of Defense.

Representative HOLIFIELD. Would you say that in your best opinion if there is going to be considerable disposal in the low ocean depths of radioactive wastes there should be, in advance of any policy such as that, a thorough exploration of this subject?

Dr. REVELLE. Yes, indeed I would, sir. I would urge it very strongly indeed for the welfare of mankind.

Chairman DURHAM. How many people are with the Scripps Institution?

Dr. REVELLE. What is the total staff of the Scripps Institution?

Chairman DURHAM. Yes.

Dr. REVELLE. About 550 people.

Chairman DURHAM. Are all of them primarily concerned with this research?

Dr. REVELLE. At the present time, at least, not more than 15 out of that number are involved with this kind of problem. It is a very small percentage, and I think the percentage should be increased. I think it could be increased.

Chairman DURHAM. You do not have any contract with AEC?

Dr. REVELLE. We have a small contract with the AEC, yes.

Representative HOLIFIELD. In this field, or a different field?

Dr. REVELLE. In this field, yes. We get a lot of support from the Federal Government. The total budget of the institution is about $3½ million a year, of which two-thirds comes from the Federal Government.

There is one other very minor point I would like to make. It looks as if some of the radioactivity in the ocean—artificial radioactivity—comes from the land. The ocean is a great hole in the ground, and at least in our part of the ocean, off the California coast, there is a

very considerable increase in the radioactivity of the sea water after a rainfall. This increase seems to be due to fission products almost entirely. So we have here an example of the complicated cycle of these things.

The surprising thing about it is that we have not yet been able to find any cesium or strontium in the water off our coast. Particularly the cesium is a curious deficiency because we have been looking for it with a device that ought to detect it. It looks as if cesium is trapped in the soil and does not run off with the other fission products.

I have kept you gentlemen too long. Thank you very much.

Chairman DURHAM. What is the opinion for that increase in the sea water off the west coast?

Dr. REVELLE. It come from the fallout which has settled on the land and washed into the ocean. At least that is our present opinion. But this opinion needs to have a lot more substantiation. This is simply a hypothesis. It is kind of interesting because it closes the cycle from the ocean explosion to the air to the land and back to the ocean.

Representative HOLIFIELD. Dr. Revelle, you have given us a most interesting presentation here today, and I am only sorry that the full membership of the committee could not be here to hear this. You understand that we have important legislation in both bodies today. Mr. Durham and I have been staying with this and missing a lot of votes on amendments which we hope to pick up tomorrow when we have our record votes. Thank you very much.

Dr. REVELLE. I certainly appreciate the chance of appearing here.

Representative HOLIFIELD. The meeting will reconvene in this room tomorrow morning at 10 o'clock, and we will have Dr. Merril Eisenbud of the New York Operations Office of the Atomic Energy Commission, Dr. Kulp of Columbia University, and Dr. Neuman of the University of Rochester School of Medicine and Dentistry. The subject will be a detailed discussion of the occurrence of strontium 90 and cesium 137 in the atmosphere, and biosphere, and its uptake and behavior in man.

Until tomorrow at 10 we stand adjourned.

(Thereupon at 5:20 p. m., Tuesday May 28, 1957, a recess was taken until Wednesday, May 29, 1957, at 10 a. m.)

THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN

WEDNESDAY, MAY 29, 1957

CONGRESS OF THE UNITED STATES,
SPECIAL SUBCOMMITTEE ON RADIATION
OF THE JOINT COMMITTEE ON ATOMIC ENERGY,
Washington, D. C.

The special subcommittee met, pursuant to recess, at 10:10 a. m., in the caucus room, Senate Office Building, Hon. Chet Holifield, chairman of the subcommittee, presiding.

Present Representatives Holifield, Durham (chairman of the joint committee), Price, Van Zandt; Senators Anderson, Knowland, Hickenlooper, and Bricker.

Also present: Professional staff members: James T. Ramey, executive director; George E. Brown, Jr., Hal Hollister, staff technical adviser, and Paul C. Tompkins, consultant.

Representative HOLIFIELD. The subcommittee will be in order.

This morning we have a notable array of witnesses. We have several witnesses, and we plan to add on additional witnesses from the Walter Reed Institute of Research to our list of this morning, provided the time allows. But before we call the first witness to the chair, I intend to make a short statement.

This committee and its chairman, under the direction of the committee, is trying to hold an objective and fair hearing. We are trying to bring to this record scientific opinion on the different facets of nuclear weapon fallout, and of the scientific problems that are pertinent thereto.

There will, of necessity, be controversial opinions stated; and this is as it should be in the scientific world, because different scientists on their own responsibility and integrity certainly have a right to be heard.

We do not want to get into the field of controversy with anyone as a committee, but there was called to my attention this morning a release by the Atomic Energy Commission in regard to this question of a clean or dirty bomb.

In the first place, the Atomic Energy Commission violated its own rules by not preparing and submitting to the committee its release 24 hours in advance of its release. We do not intend to get into this question at this time, and into a controversy with the Commission, but the record will stand as it has been given; the remarks of Dr. Graves will stand as those of the man most qualified to give an opinion on the cleanness or the dirtiness of nuclear weapons, and at the proper time there will be other evidence brought forward on this subject.

93299°—57—pt. 1——36

Our first witness this morning is Mr. Merril Eisenbud of the New York Operations Office of the Atomic Energy Commission. The subject this morning is "A Detailed Discussion of the Occurrence of Strontium 90 and Cesium 137 in the Atmosphere, Biosphere and Its Uptake and Behavior in Man."

Mr. Eisenbud has a notable record in the scientific world.

Mr. Eisenbud, proceed please.

STATEMENT OF MERRIL EISENBUD, MANAGER, NEW YORK OPERATIONS OFFICE, ATOMIC ENERGY COMMISSION [1]

Mr. EISENBUD. Thank you, Mr. Chairman.

If it pleases the committee, I would like to submit the prepared text of my statement, which is entitled "Measurement of Strontium 90 in Geophysical and Biological Materials," for the record of the proceedings.

Representative HOLIFIELD. Without objection, it shall be received.

(The statement referred to follows:)

UNITED STATES ATOMIC ENERGY COMMISSION,
NEW YORK OPERATIONS OFFICE,
New York, N. Y.

Summary of remarks by Merril Eisenbud, Manager, New York Operations Office and Director, Health and Safety Laboratory before hearings conducted by the Joint Congressional Committee on Atomic Energy on the Nature of Radioactive Fallout and Its Effects on Man, May 1957, Washington, D. C.

MEASUREMENT OF STRONTIUM 90 IN GEOPHYSICAL AND BIOLOGICAL MATERIALS

INTRODUCTION

The studies being reported on are directed toward a full understanding of the physical and biological behavior of the strontium 90 produced in nuclear detonations. The fundamental questions to be answered by consideration of the data are:

1. How much strontium 90 has been deposited on the earth's surface?
2. How much strontium 90 from detonations to date remains suspended in the upper atmosphere and how long will it take to precipitate?
3. How much strontium 90 will human skeletons contain when they are in equilibrium with the expected levels of strontium 90 in soil?

The properties that make strontium 90 the most hazardous of the nuclides formed in the fission process are its long half-life (28 years) and its chemical similarity to calcium. Because of its resemblance to calcium, strontium 90 may be assimilated by biological processes. If strontium is ingested by human beings in food or water, it will deposit, like calcium, in the skeleton.

Samples are collected throughout the world for strontium 90 analyses. Many of these are sent to the United States for analyses, but others, in increasing numbers, are analyzed in the laboratories of other lands by the many scientists whose data, like our own, are routinely submitted to the United Nations Committee on the Effects of Radiation.

Monitoring for radiostrontium can be divided conveniently into studies of its geophysical and biological distribution. Under the former classification are collected those samples which give us an understanding of the behavior of radiostrontium from its formation in the fireball to its deposition on the surface of the earth and incorporation into soils. The biological studies trace the movements of strontium 90 from the soils and waters through the flora and fauna of the oceans, pastures, and farms, to the skeleton of man.

TYPES OF SAMPLES

Soils.—A soil sample, expertly selected, can represent the accumulated fallout at a given location. An ideal sampling site is considered to be an open, level area, undisturbed by cultivation and covered by grass or simple vegetation covering to immobilize the surface. The most common division of sampling is to collect the top 2 inches and the 2-to-6-inch layer separately. The known area and the measured weight of sample allow the strontium 90 measurements to be converted to terms of millicuries per square mile.

Experimental work has shown that the movement of strontium 90 in the soil is slow enough that adequate samples can be obtained. For example, from 75 to 80 percent of the strontium 90 found in the soil is in the top 2 inches. The disadvantage of soil samples is in the complex and time-consuming nature of the analysis.

Collections in open pots.—Stainless steel pots, with a face area of about 1 square foot, are finding increasing application in fallout sampling both here and abroad. The collected precipitation and dust are analyzed for strontium 90 at intervals, usually on a monthly basis.

Gummed film collections.—The need for a simple collecting technique suitable for network operations, where large numbers of collecting stations employ untrained personnel, led to the development of the gummed film collector. This collector has an adhesive surface of 1 square foot which is exposed for 24 hours. A network of up to 200 stations collecting daily samples has been operated by the Health and Safety Laboratory since 1951. Samples are mailed to the laboratory where the analyses are performed.

Atmospheric sampling.—The fission products, including strontium 90, are in particulate form in the atmosphere and the most common air sampling procedure is to draw a large volume of air through a filter. This type of sampling has been carried out at the earth's surface, in the lower atmosphere by jet planes, and in the stratosphere by balloons.

BIOLOGICAL DISTRIBUTION

The chemical similarity of strontium and calcium makes it desirable to use the strontium 90: Ca ratio in tracing strontium 90 from soils to man. A useful unit of strontium 90 contamination, first proposed by Libby, is the micromicrocurie of strontium 90 per gram of calcium ($\mu\mu c$/gmCa).

The three principal types of samples taken for analysis are (1) vegetation, including both animal and human food, (2) milk, and (3) human bone.

Vegetation.—Strontium 90 may occur in vegetation in either of two routes. Strontium 90 from the soil may be taken up by the root system and incorporated into the plant. In addition, fallout may be directly deposited on the plant.

Milk.—The major source of body calcium in the United States is milk, hence its analysis has received considerably more attention than that of any other foodstuff although other foods may have a higher strontium 90 to Ca ratio. Actually, cow's milk contains less strontium per gram of calcium than do the vegetables which comprise the balance of our calcium intake. This is because biological processes in general tend to discriminate against strontium. Thus the strontium 90 has been selectively eliminated by 2 stages—the vegetable and the cow—in the case of milk and only 1 stage in the case of a vegetable. Milk seems to be the most practical index of human exposure to strontium 90 because it is the source of most of the calcium in the skeletons of American adults, and it is a material which is relatively easy to sample.

Human bone.—Analyses of human bone afford a direct measure of the strontium 90 level at a given time. These samples show the lowest levels of strontium 90 of any biological material being analyzed. Since human bone is not yet in equilibrium with the strontium 90 of the environment, however, measurements made at the present time are only of value when viewed in relation to other materials, particularly human food and the present and predicted levels of strontium 90 on the earth's surface.

DISCUSSION OF FINDINGS

Estimates of fallout obtained by analyzing soil samples are lower than those obtained by gummed film collection but the reason why this is so is not clear. One megacurie, being intermediate between the estimates for gummed paper and for soil, is perhaps the most reasonable approximation of the total amount of strontium 90 deposition on the earth by delayed fallout in mid-1956.

It is also noted that the soil data indicate a greater degree of latitudinal variation than the gummed film data. In the latter case the mean deposition in the North Temperate Zone is slightly high in relation to the somewhat uniform deposition elsewhere in the world. The data derived from soil samples likewise indicate a higher deposition in the North Temperate Zone but there is less uniformity elsewhere in the world and a north-south gradient is quite evident.

STRATOSPHERIC RESERVOIR

An estimate of the future distribution of strontium 90 may be obtained from the sampling data plus knowledge of the amount of strontium 90 suspended in the upper atmosphere, and the rate at which it precipitates to earth's surface.

It is apparent that the rate of precipitation of the strontium 90 must be considered in any estimation of future hazard. If the time of descent was infinitely great, the strontium 90 would decay before it reached the earth's surface and it would not constitute a potential hazard. Actually, we have learned that the time of descent is relatively short in relation to the half-life of strontium 90. It is estimated that the average residence time is approximately 10 years (equivalent to a half-life of 7 years). It is possible this estimate is too long and the average life is as little as 6 to 7 years (half-life about 4½ years).

This discussion of the foreseeable levels of strontium 90 will thus be simplified by the assumption that the material now contained in the stratospheric reservoir will be completely deposited on the earth's surface before any radioactive decay has occurred. Moreover, it will be assumed that the geographical distribution in the future will follow approximately the same distribution as the deposition of stratospheric debris in the past. This will tend to introduce an error on the side of safety since it would be expected that future fallout would be more uniform than in the past.

FUTURE ESTIMATE OF STRONTIUM 90 IN MAN

It will be assumed that essentially all of the 2.4 megacuries of strontium 90 stored in the stratosphere in mid-1956 will be deposited on earth's surface by about 1970 and that stratospheric fallout will be distributed in approximately the same pattern as the past.

This discussion of future levels of strontium 90 in man will be based on data for a region in Northeastern United States where the deposition of strontium 90 in the fall of 1956 averaged 20 millicuries per square mile. Of this, about 6 mc/mi^2 is estimated to be tropospheric fallout from tests prior to mid-1956. The stratospheric fallout may thus be estimated as 14 millicuries per square mile. This was the level which existed when the worldwide deposition of strontium 90 was about 1 megacurie. It is estimated that when the 2.4 megacuries then in the stratosphere has deposited, the deposition on this milkshed will be 45 millicuries per square mile, about 2.3 times the level in mid-1956.

To define the potential risk from a given distribution of strontium 90 on the surface of the earth requires that the distribution be quantitatively related to the skeletal burden of strontium 90 of a human population in dietary equilibrium with the soil from which its nourishment is derived. This equilibrium is already established for a variety of radioactive elements normally present in the earth's crust. For example, the average upper foot of soil in the United States contains about 1,000 millicuries of radium per square mile. The average adult skeleton in this country contains about 10 microcuries of radium, resulting from assimilation of this trace element from foods and water. Thus, the value of 10^{-4} microcuries of radium represents the amount deposited in the skeletons of the populations whose mineral metabolism is in equilibrium with the soil minerals.

Freshly deposited strontium 90 takes a relatively long time to complete the biological route to bone since bone being formed at the present time utilizes calcium which left the soil in months gone by. In addition, storage of cattle fodder and hold-up of human foods in commercial distribution lead one to expect the human strontium 90 burden to lag in time behind a given soil concentration. Equilibrium can be expected to be achieved over a period of years but not over a period of months.

During periods of actual fallout the concentration of strontium 90 in milk originates from the soil by normal root uptake or it may short circuit the soil through deposition directly on the leaf and ingestion by the cow.

At present, the extent to which strontium 90 occurs in milk as a result of direct deposition on leaves is not known. This fraction presumably diminishes with time as the accumulation in soil increases and the rate of fallout remains approximately constant. In contrast, the strontium 90 of the soil constitutes a relatively long lived reservoir for future uptake. Diminution will result only from radioactive decay or if the strontium 90 is leached beyond the root zone. For the purpose of this discussion it will be assumed that all of the strontium 90 in milk is metabolized by way of the roots. This is a conservative assumption which tends to exaggerate the forecast of future levels.

Milk from the milkshed previously discussed has been analyzed routinely since early 1954. The strontium 90 level of this milk averaged 3.5 $\mu\mu c/g$ Ca in the period just preceding the sampling of the soils in October 1956. If we neglect the effect of fresh fallout, and further assume that the strontium 90 in milk is proportional to the amount in soil, the future level may be estimated as $35 \times 2.3 = 8 \mu\mu c$ Sr-90/g Ca. This prediction is in good agreement with the value of 8.3 $\mu\mu c/g$ Ca which was similarly estimated by the data available from this milkshed in the summer of 1955.

Based on the data now available a child being nourished on milk containing $8 \mu\mu c$ Sr-90/g Ca would be expected to develop a skeleton containing strontium 90 in somewhat lower concentrations than this value (because the human metabolism descriminates in some measure against strontium,) possibly higher than 4 $\mu\mu c$ Sr-90/g Ca. Thus 4-6 $\mu\mu$/g Ca may be said to be the highest foreseeable value to be attained from a diet containing 8 $\mu\mu c$ Sr-90/g Ca.

Assuming 5 $\mu\mu c$ Sr-90/g Ca to be the maximum value to be attained, one can calculate this amount of strontium 90 will deliver a dose of 0.5 rads to the skeleton over a lifetime of 70 years. This compares with a normal skeletal irradiation of 7 to 30 rads resulting from potassium 40, carbon 14, cosmic rays, terrestrial gamma radiation and radium. The maximum foreseeable value of 5 $\mu\mu c$ Sr-90/g Ca is thus equivalent to 1.5 to 6 percent of the dose from natural sources of skeletal irradiation.

It should be noted that this estimate includes a number of assumptions which are deliberately conservative. No allowance has been made for radioactive decay before the strontium 90 descends from the stratosphere. This may diminish the amount of available strontium 90 by about 25 percent. The assumption that all of the strontium 90 in milk originated by root uptake, is another conservative assumption. The combined effect of these and other safety factors is apt to be appreciable.

The question has been raised as to whether a discussion of average fallout values is adequate to define the upper limit of hazzard to people exposed to unusually heavy fallout. In this connection it is worth noting that as the data continue to accumulate from every corner of the globe the large deviations from average are in the safe direction. Whereas fallout values greater than twice the mean are rarely reported in any given region, it is not uncommon to observe values which are of the order of 10 percent of the average.

This forecast has been made on the basis of data from Northeastern United States. How applicable are these data to other parts of the United States or of the world? Summaries of the concentration of strontium 90 in milk as observed in 6 domestic and 2 foreign sources of supply as well as the data from the fallout measuring systems described earlier, indicate that the strontium 90 content of dietary calcium might be higher in certain areas. A factor of three applied to the estimates for northeastern United States should be adequate, however, to bracket the highest foreseeable value, from tests to date, in any region of the United States.

I. Measurement of Strontium 90 in Geophysical and Biological Materials

By Merril Eisenbud for presentation at hearing on the Nature of Radioactive Fallout and its Effects on Man

INTRODUCTION

The properties that make strontium 90 the most hazardous of the nuclides formed in the fission process are its long half-life (28 years) and its chemical similarly to calcium. Because of its resemblance to calcium, Sr-90 may be

assimilated by biological processes. If strontium is ingested by human beings in food or water, it will deposit, like calcium, in the skeleton.

Investigation of the potential hazard from contamination of soils and the biological food chains by Sr–90 began very early in the United States atomic energy program. The first studies, associated with the wartime weapons-development program, were theoretical and were designed to identify the principal parameters which influence the long-range effects of nuclear detonations. It was clear, from the start, that studies of radioactive fallout, and of the ultimate fate of Sr–90 in particular, would require the application of knowledge from a wide assortment of the physical and biological sciences. The initial theoretical studies provided a valuable basis for the experimental approach to the problem that became possible with the programs of weapons testing that began in 1948 and have continued intermittently to the present time.

The Sr–90 studies have increased in scope and complexity, and the overall program has, for some years, been global in extent, involving physical, chemical, and biological investigations on land, in the oceans, and in the air. Known as Project Sunshine and directed at a full understanding of the physical and biological behavior of the Sr–90 produced in nuclear detonations, these studies are concerned with an unprecedented variety of scientific questions. From the standpoint of its vast geographic dimensions and the variety of scientific mechanisms involved in the investigation, Project Sunshine rivals the most comprehensive scientific studies ever undertaken.

The factors that influence the behavior of Sr–90 begin in the complex physics and chemistry of the fireball and the mushroom-shaped cloud which forms after a nuclear detonation. The height of the burst aboveground, the nature of the terrain, and the particle size of the soil and debris sucked into the fireball all influence the fallout pattern.

When the particles descend to the earth's surface, they leave the domain of the meteorologist and become involved in the physics, chemistry, and biology of the soil. How soluble is the Sr–90 in fallout? Does it leach from the soil? At what rate is it incorporated into plants, and how can this rate be expressed quantitatively as a function of type of soil and type of plant? These are a few of the questions that have been studied in tracing the Sr–90 into the first of the biological links in the food chain between soil and man. The answers to these and many more questions have been obtained by many investigators working in many laboratories throughout the country.

From its formation in a nuclear detonation until it is metabolized by man, the path of a strontium 90 atom is long and tortuous. Understanding of its route has come from studies which know none of the bounds of any one of the conventional scientific disciplines. The phenomenology of strontium 90 in fallout can be described only in the combined languages of all the principal combined sciences—geophysics, physical chemistry, biophysics, and biological chemistry. Samples are collected throughout the world for strontium 90 analyses. Many of these are sent to the United States for analyses, but others, in increasing numbers, are analyzed in the laboratories of other lands by the many scientists whose data, like our own, are routinely submitted to the United Nations Committee on the Effects of Radiation.

Monitoring for radiostrontium can be divided conveniently into studies of its geophysical and biological distribution. Under the former classification are collected those samples which give us an understanding of the behavior of radiostrontium from its formation in the fireball to its deposition on the surface of the earth and incorporation into soils. The biological studies trace the movements of strontium 90 from the soils and waters through the flora and fauna of the oceans, pastures, and farms, to the skeleton of man. A summary of the AEC sampling program is given in table I.

SAMPLING FOR GEOPHYSICAL DISTRIBUTION

Except for immediate fallout in the area of detonation, the original fission products are injected into the troposphere or stratosphere and are geographically distributed by the winds. Radioactive materials are brought down to the surface by precipitation, settling, and, to a lesser extent, by air turbulence.

It is desirable to measure the rate of fallout, its accumulation, and the atmospheric reservoir of material yet to be deposited on earth's surface. The samples currently taken for this program include soils, sea water, collections of fallout in open pots and on gummed film, and collections of atmospheric dust on filters.

SOILS

A soil sample can represent the accumulated fallout at any given location. There are many criteria to be met to insure that a soil sample is representative. An ideal sampling site is considered to be an open, level area, undisturbed by cultivation and covered by grass or simple vegetation covering to immobilize the surface. Drainage slopes, silted areas or other unusual drainage conditions should be avoided. Samples are collected with soil augers to give definite areas and depths. The most common division of sampling is to collect the top 2 inches and the 2- to 6-inch layer separately. The known area and the measured weight of sample allow the strontium 90 measurements to be converted to terms of millicuries per square mile.

Removal of strontium 90 from a soil sample is a difficult problem because the relatively low levels of activity currently found require use of very large samples. At present 2 to 4 pounds of soil are taken for analysis and this makes the usual procedure of completely dissolving the soil by fusion a practical impossibility. Thus although the fusion technique is the only method certain to remove all strontium 90 from the soil it has been necessary to study other methods for strontium 90 extraction. After considerable experimentation, procedures that agree satisfactorily with the fusion technique have been developed. These involve the extraction of the strontium 90 by electrodialysis or by hydrochloric acid leaching without completely dissolving the soil. Present evidence leads us to believe that the acid leach removes 85 percent or more of the strontium 90 and the electrodialysis at least 75 percent. Some early analyses were obtained by ammonium acetate leaching of the soil, but this method is now felt to be inadequate, and none of the data presented here were obtained in this way.

The chemical analysis following extraction requires separation of the strontium 90 from the inactive bulk constituents of the extract and from other radioactive isotopes, which include the natural constituents of the soil and other fission products, including strontium 89.

The soil sample offers a practical means of measuring the accumulation of strontium 90 at a particular location. Experimental work has shown that the movement of strontium 90 in the soil is slow enough that adequate samples can be obtained. For example, from 75 to 80 percent of the strontium 90 found in the soil is in the top 2 inches. The disadvantage of soil samples is in the complex and time-consuming nature of the analysis.

SEA-WATER SAMPLES

Since approximately two-thirds of the earth's surface is covered by the oceans, a complete accounting for strontium 90 deposition requires sampling of the oceans. However, in contrast to soils, the strontium 90 in the oceans is distributed through a depth of several hundred feet, at least. The analytical requirements for this type of sample have been beyond the capabilities of the participating laboratories except for samples taken near the Pacific Proving Grounds shortly after a major weapons test. Therefore, studies of distribution in the ocean have been limited to measurements of total fission products and their transport by ocean currents as a function of time. Such measurements of mixed fission products do not give reliable estimates of strontium 90 in sea water since the fission products may be fractionated by solubility, precipitation, and sedimentation.

Mixed fission products in sea water are concentrated by coprecipitation of the majority of the isotopes with various carriers such as iron hydroxide or calcium carbonate. The activity levels of interest are high enough so that conventional counting equipment can be used for measurement. Extension of the sensitivity by measurement with low background counters would probably not be justified in terms of the overall accuracy of the determination.

FALLOUT COLLECTIONS IN OPEN POTS

Stainless-steel pots, with a face area of about 1 square foot, are finding increasing application in fallout sampling. Other types of vessels have been tried and are currently used in some parts of the monitoring program in this country and abroad. The collected precipitation and dust can be analyzed for strontium 90 at intervals, usually on a monthly basis. In sharp contrast to the soil samples, the residues submitted to analysis are essentially free of nonradioactive material. The monthly increment in fallout is readily determined from

these samples, while it is only feasible to measure annual increments in soil samples.

The analysis of pot collections requires the separation of strontium 90 from the small amounts of inert material and from other isotopes of mixed fission products. The deposition of naturally occurring radioisotopes during a month is negligible. The levels currently found are such that low background counting equipment is required for satisfactory analysis.

Collection in pots is open to the criticism that more fallout may be collected than would be deposited in the open air. This is caused by inpaction on the inner sides of the vessel. Studies are underway to determine the best shape and size of vessel for collections. However, it should be noted that comparison of annual pot increments with soil increments have shown good agreement.

GUMMED FILM COLLECTIONS

The need for a simple collecting technique suitable for network operations, where large numbers of collecting stations employ untrained personnel, led to the development of the gummed film collector. This collector has an adhesive surface of 1 square foot which is exposed for 24 hours. A network of up to 200 stations collecting daily samples has been operated by the Health and Safety laboratory since 1951. Samples are mailed to the laboratory where the analyses are performed. It is not possible to determine Sr–90 directly in gummed film—first, because the amount of Sr–90 deposited in 24 hours is to a small, and second, because during rainfall a variable fraction of the Sr–90 is lost by preferential solubility. The Sr–90 component has in the past been estimated by calculation from the mixed product values. In addition, an estimate has been made of the gamma dose resulting from this fallout. The increased weapons test activity has made these calculations extremely difficult and the methods originally followed have been found inadequate. At the present time a new calculation procedure has been devised and is being tested.

The gummed film samples are ashed to reduce their area and the total mixed fission product activity is measured with automatic beta geiger counters. The activity measurement and the weather data for each sample are entered on IBM cards for calculation and tabulation. The results of this work have been presented in several summary papers.

The gummed film has two major disadvantages. First, it does not allow direct measurement of Sr–90 fallout, and second, from two standpoints it is not a perfect collector of fallout. There are definite indications that there is some wash off of radioactive material during precipitation. When there is no precipitation the gummed film may collect more activity than would be found on a square foot of a perfect collector since some airborne dust, which would not settle ordinarily, may be scavenged by the gummed surface. Experiments in several locations, however, have shown an average collection efficiency of about 60 percent and this value is used to correct the measured values obtained in the laboratory. This will be discussed further in a later section.

The advantage of gummed film is its extreme simplicity as a collector and its adaptability to network operation with a central processing facility. In addition, the fact that the gummed film can be measured on a daily basis offers some advantage in detecting the time of arrival of radioactive material. This is particularly useful in the estimation of the low levels of total gamma dose associated with fallout, since the gamma dose at any given location is sensitive to the time of arrival of the fission products.

ATMOSPHERIC SAMPLING

The fission products, including Sr–90, are in particulate form in the atmosphere and the most common air sampling procedure is to draw a large volume of air through a filter. The dust on the filter can then be analyzed for Sr–90 and the atmospheric concentration can be obtained from a knowledge of the volume of the air sampled. This type of sampling has been carried out at the earth's surface, in the lower atmosphere by jetplanes, and in the stratosphere by balloons. The major difference between these samples lies in the amount of air that can be sampled and thus in the activity level which can be collected on a filter.

The analysis consists of the separation of Sr–90 from the inactive constituents of the dust on the filter and the separation from natural radioactive materials and other fission products. Activity levels at the surface or in the lower atmosphere are sufficient that simple beta geiger counters can be used. The

volume of air that can be sampled in the stratosphere, when converted by calculation to normal temperature and pressure, is small. Consequently a small amount of particulate material is collected and low background counters are an absolute necessity.

Estimation of the atmospheric reservoir of Sr-90 is needed to predict the level which will be finally deposited on the ground when all the material is deposited. Because of nonuniformity in the distribution of the radioactive debris in the atmosphere, both laterally and vertically, the sampling program must be very extensive to develop a reliable picture.

Air samples at the surface of the earth are the simplest to obtain but are the most heavily influenced by local meteorological conditions. A better estimate can be obtained from stratospheric samples which are the most costly in terms of both sampling and analysis.

At the present time monthly samples at four stratospheric altitudes are being taken at Minneapolis, Houston, Panama Canal Zone, and at one station in the Southern Hemisphere. This pilot program is designed only to determine the degree of uniformity and thus the extent of sampling required for complete evaluation of the atmosphere.

BIOLOGICAL DISTRIBUTION

The chemical similarity of strontium and calcium makes it desirable to use the Sr-90:Ca ratio in tracing Sr-90 from soils to man. A useful unit of Sr-90 contamination, first proposed by Libby, is the micromicrocurie of Sr-90 per gram of calcium ($\mu\mu$c/gmCa). For convenience this unit is frequently referred to as the "Sunshine unit."

The biological distribution of Sr-90 is being studied in its entirety and these investigations have produced a wide variety of data. For this discussion, which is concerned primarily with an evaluation of the potential human hazard from Sr-90, the presentation will be simplified greatly by reviewing only the principal sources of human calcium. The presently observed and predicted future levels of Sr-90 in these foods offer a convenient means of estimating the amounts of Sr-90 that the human skeletons of the future are expected to contain.

In the United States, and many western countries, the main calcium source is milk, with leafy vegetables supplying the majority of the balance. In some areas, such as southeastern United States, this ratio may be reversed. The sources of calcium in countries of the world is under study by the Food and Agricultural Organization and data on the non-milk-drinking populations is slowly becoming available.

The three principal types of samples taken for analysis are (1) vegetation, including both animal and human food, (2) milk, and (3) human bone.

VEGETATION

Sr-90 may occur in vegetation in either of two routes. Sr-90 from the soil may be taken up by the root system and incorporated into the plant. In addition, fallout may be directly deposited on the plant. Part of this latter material may be washed off by rain but a considerable portion apparently is retained. The relative distribution of Sr-90 in the plant and on the outer surfaces may be quite variable, depending on the amount of fallout and the type of soil.

The type of vegetation selected depends on whether it represents food for animals or for humans. For human foods the samples can be taken from the consumer market. The analysis of vegetation is simpler than for soils or for fallout collections since the amount of inactive material is small related to the amount of Sr-90, and because the plant discriminates against many of the radioactive isotopes. Analysis still requires, however, separation of Sr-90 from the inactive constituents of the plant ash and from other radioisotopes which are present.

MILK

The major source of body calcium in the United States is milk, hence its analysis has received considerable more attention than that of any other foodstuff although other foods may have a higher Sr-90-to-Ca ratio. As a matter of fact, cow's milk contains less strontium per gram of calcium than do the vegetables which comprise the balance of our calcium intake. This is because, as noted by other speakers, biological processes in general tend to discriminate against strontium. Milk contains less strontium per gram of calcium because the calcium has passed through two biological processes. The strontium has

passed through the vegetable and then through the cow. Thus the Sr-90 has been selectively eliminated by 2 stages in the case of milk and only 1 stage in the case of a vegetable. Nevertheless, milk seems to be the most practical index to human exposure to Sr-90 because it is the major source of calcium in the skeletons of American adults. Moreover, it is a material which is relatively easy to sample, and the samples represent the pooling of milk from large geographical areas.

Monthly analyses of milk samples are available from 6 major milksheds in the United States, for periods ranging from 1 to 4 years. The sampling procedures have been designed to follow the exposure level of the human population at the location rather than to follow an individual farm or even an individual processing plant.

The determination of Sr-90 in milk is a relatively simple procedure, since the cow discriminates sharply against other fission products. The main analytical problem is the separation of Sr-90 from the large amount of calcium present.

The chief advantage of following milk as a monitoring device is that it yields an immediate estimate of the amount of Sr-90 which man will ingest. This is more direct and more reliable than attempting to predict the movement of Sr-90 to man from analyses of fallout or of soil.

HUMAN BONE

Analyses of human bone afford a direct measure of the Sr-90 level at a given time. However, as previously mentioned, human bone is not yet in equilibrium with the Sr-90 of the environment. Thus, measurements made at the present time are only of value when viewed in relation to other materials, particularly human food and the present and predicted levels of Sr-90 on the earth's surface.

Human bone samples show the lowest levels of Sr-90 of any biological material being analyzed. This means that a large sample of bone is required for analysis and such specimens are not always readily obtainable. The extensive program at the Lamont Geological Observatory has yielded several hundred autopsy specimens from all over the world. Dr. Kulp, who is in charge of this work at Lamont, will report on it in detail.

The analysis of bone requires the separation of Sr-90 from large quantities of calcium but only negligible amounts of other radioisotopes are present. The current levels require not only low background counting equipment but the most extreme care in the prevention of contamination of samples with other radioactive materials.

DISCUSSION OF FINDINGS

We have seen that many kinds of samples are being collected routinely from a large number of locations, and that the Sr-90 in these samples serves as a tracer for the study of many physical, chemical, and biological processes. In this discussion, an effort will be made to simplify the analyses of the data and to deal only with those portions of the overall Sunshine program that are concerned with an estimate of the human hazard from Sr-90.

The fundamental questions which must be answered are these:

1. How much Sr-90 has been deposited on the earth's surface?
2. How much Sr-90 from detonations to date remains suspended in the upper atmosphere and how long will it take to precipitate?
3. How much Sr-90 will human skeletons contain when they are in equilibrium with the expected levels of Sr-90 in soil?

DEPOSITION OF SR-90 IN EARTH

As noted earlier there are two basic procedures by which the widespread deposition of Sr-90 can be documented. The first, and the most direct, is by the collection of soil samples and their analysis for Sr-90.

The soil analyses for the year 1956 are plotted in figures 1 and 2, which give the estimates of Sr-90 deposition in millicuries per square mile. Similar data have been obtained on the basis of samples collected from the gummed film network. These data are summarized in figures 3 and 4 which give the estimated cumulative Sr-90 distributions as of July 1, 1956. In recent months a third method has been adopted, utilizing pots which have been located at 21 stations throughout the world but too few data are available to justify presentation at this time.

It will be noted that, for most of the world, the estimates of fallout obtained by analyzing soil samples are lower than those obtained by gummed film collection. The differences can be seen in table 4 which summarizes the observation of both the soil sampling and the gummed film network by zones. The estimated worldwide fallout of Sr–90, based on the gummed film samples, is 1.5 megacuries compared to 0.88 megacurie as estimated by soil samples. It is also noted that the soil data indicate a greater degree of latitudinal variation than the gummed film data. In the latter case the mean deposition in the North Temperate Zone is slightly high in relation to the somewhat uniform deposition elsewhere in the world. The data derived from soil samples likewise indicate a higher deposition in the North Temperate Zone but there is less uniformity elsewhere in the world and a north-south gradient is quite evident.

The reason why the soil samples yield lower values in most locations is not clear. The integrated fallout as estimated by soil analyses is 59 percent of the value obtained from the gummed film observation. As noted earlier it is possible that the Sr–90 is incompletely removed from the soil by chemical analysis and this may account for some, but certainly not all, of the difference. The gummed film tends to yield results which are comparable to the Sr–90 measurements of pot samples but it is possible that both the pot and the gummed film tend to concentrate fallout, particularly on dry, windy days. It is also possible that some of the Sr–90 has been leached beyond the sampling depth. At the present time, there is insufficient knowledge to explain the difference between the two methods. One megacurie, being intermediate between the two estimates, is perhaps the most reasonable approximation of the total amount of Sr–90 deposition on the earth by delayed fallout in mid-1956.

The test firings in Nevada only partly account for the relatively elevated deposition in the North Temperate Zone. There is evidence that much of the differentiation between the North Temperate Zone and the rest of the world can be attributed to the preferential fallout in this region from 1954 series in the Pacific (Operation Castle).

STRATOSPHERIC RESERVOIR

An estimate of the future distribution of Sr–90 may be obtained from the above data plus knowledge of the amount of Sr–90 suspended in the upper atmosphere, and the rate at which it precipitates to earth's surface. The direct method of measuring the stratospheric reservoir is to obtain samples, using balloons or high-flying aircraft. This has been done intermittently since 1953 but the data are too few to permit one to estimate by this method, with any degree of confidence, the total inventory of stratospheric Sr–90.

Using a more indirect procedure, Libby suggested a value of 2.4 megacuries of Sr–90 in the fall of 1956. This estimate is based not on direct measurements in the stratophere, but rather on what might be described as material balance studies. The amount of Sr–90 produced in detonations, to date, can be estimated. Estimates of the amounts of Sr–90 that are deposited in the intense fallout in the vicinity of a detonation are available from extensive investigations conducted during the test programs in Nevada and in the Pacific. The total strontium produced in a detonation, less the Sr–90 which falls out in the immediate vicinity of the detonation, gives the total inventory of Sr–90 that is available for subsequent deposition at places remote from the site of detonation.

It is apparent that the rate of precipitation of the Sr–90 must be considered in any estimation of future hazard. If the time of descent was infinitely great, the Sr–90 would decay before it reached the earth's surface and it would not constitute a potential hazard. Actually, we have learned that the time of descent is relatively short in relation to the half-life of Sr–90. Libby has estimated that the average residence time is approximately 10 years. In mathematical terms this would be equivalent to a half-life of 7 years. It is possible this estimate is too long and the average life is as little as 6–7 years (half-life about 4½ years).

Our discussion of the foreseeable levels of Sr–90 will thus be simplified by the assumption that the material now contained in the stratospheric reservoir will be completely deposited on the earth's surface before any radioactive decay has occurred. Moreover, it will be assumed that the geographical distribution in the future will follow approximately the same distribution as has been true of the deposition of stratospheric debris in the past. This will tend to introduce in error on the side of safety since it would be expected that future fallout will be more uniform than in the past.

FUTURE ESTIMATE OF SR–90 IN MAN

As noted earlier, it will be assumed that essentially all of the 2.4 megacuries of Sr–90 stored in the stratosphere in mid-1956 will be deposited on earth's surface. This will have occurred by about 1970. It will be further assumed that stratospheric fallout in the future will be distributed in approximately the same pattern as the past.

This discussion of future levels of Sr–90 in man will be based on data for Northeastern United States. The fallout levels, as estimated by soil analyses in late 1956, averaged 20 millicuries per square mile in 1 large milkshed which has been sampled since 1954. Of this, about 6 mc/mi^2 is estimated to be tropospheric fallout from tests prior to mid-1956. The stratospheric fallout may thus be estimated as 14 millicuries per square mile. This was the level which existed when the worldwide deposition of Sr–90 was about 1 megacurie. It is estimated that when the 2.4 megacuries then in the stratosphere has deposited, the deposition on this milkshed will be 45 millicuries per square mile, about 2.3 times the level in mid-1956.

To define the potential risk from a given distribution of Sr–90 on the surface of the earth requires that the distribution be quantitatively related to the skeletal burden of Sr–90 of a human population in dietary equilibrium with the soil from which its nourishment is derived. This equilibrium is already established for a variety of trace elements normally present in the earth's crust. Some of these, like potassium and radium, are radioactive, and this is reflected by the presence of these substances in the human body. For example, the upper foot of soil in the United States contains, on the average, about 1,000 millicuries of radium per square mile. The average adult skeleton in this country contains about 10^{-4} microcuries of radium, which is derived from assimilation of this trace element from foods and water. Thus, the value of 10^{-4} microcuries of radium represents the amount deposited in the skeletons of the populations whose mineral metabolism is in equilibrium with the soil minerals.

The freshly deposited Sr–90 takes a relatively long time to complete the biological route to bone. At the present time the skeletons of all but very young children were formed prior to the introduction of Sr–90 to the soil. Moreover, bone being formed at the present time utilizes calcium which left the soil in months gone by. The fact that cattle may be fed on hay many months old and the holdup of human foods in the commercial distribution system are but two of many factors which would lead one to expect the human Sr–90 burden to lag in time behind the potential value which might ultimately be expected from a given soil concentration. The human skeleton cannot be expected to respond quickly to the gradual accretion of Sr–90 by soil. Equilibrium can be expected to be achieved over a period of years but not over a period of months.

In the United States, as in a number of other parts of the world where the population derives much of its calcium from dairy products, analyses of milk for Sr–90 provide a convenient method of estimating the levels of human absorption which may be expected in the future.

During periods of actual fallout the concentration of Sr–90 in milk originates from two sources: The Sr–90 level may have been metabolized from the soil by normal root uptake or it may have short circuited the soil by having been deposited directly on the leaf with which it is ingested by the cow. The presence of the latter fraction is dependent on current fallout. If all detonations ceased, the fraction due to direct deposition on the leaf surfaces would diminish with the reduction in the rate of fallout. With the cessation of fallout this fraction would be eliminated altogether. In contrast, the Sr–90 of the soil constitutes a relatively long lived reservoir for future uptake. Diminution will result only from radioactive decay or if the Sr–90 is leached beyond the root zone.

At the present time, it is not known to what extent the Sr–90 which occurs in milk may be due to direct deposition on leaves. This fraction presumably diminishes with time as the accumulation in soil increases and the rate of fallout remains approximately constant. For our purposes it will be assumed that all of the Sr–90 in milk is metabolized by way of the roots. This is a conservative assumption which tends to exaggerate the forecast of future levels.

Milk from the milkshed previously discussed has been analyzed routinely since early 1954 (fig. 5). The Sr–90 level of this milk averaged 3.5 $\mu\mu c/g$ Ca in the period just preceding the sampling of the soils in October 1956. If we neglect the effect of fresh fallout, and further assume that the Sr–90 in milk is proportional to the amount in soil, the future level may be estimated as $3.5 \times 2.3 = 8$ $\mu\mu c$ Sr–90/g

Ca. This prediction is in good agreement with the value of 8.3 μμc/g Ca which was similarly estimated by the data available from this milkshed in the summer of 1955.

Our final problem is to estimate the burden of Sr–90 which will be attained by a population whose principal dietary source of Ca contains 8 μμc/g. As has been noted by previous speakers, it is known that human metabolism involves some measure of discrimination against strontium and in favor of calcium. Based on the data now available a child being nourished on milk containing 8 μμc Sr–90/g Ca would be expected to develop a skeleton containing Sr–90 in somewhat lower concentrations than this value but probably higher than 4 μμc Sr–90/g Ca. Thus 4–6 μμc/g Ca may be said to be the highest foreseeable value that will be attained from a diet containing 8 μμc Sr–90/g Ca. A value of 5 may be taken as the basis for discussion.

Assuming 5 μμc Sr–90/g Ca to be the maximum value to be attained, one can calculate that this amount of Sr–90 will deliver a dose of 0.5 rads to the skeleton over a lifetime of 70 years. This compares with a normal skeletal irradiation of 7 to 30 rads resulting from potassium 40, carbon 14, cosmic rays, terrestrial gamma radiation, and radium. The maximum foreseeable value of 5 μμc Sr–90/g Ca is thus equivalent to 1.5 to 6 percent of the dose from natural sources of skeletal irradiation.

It should be noted that this estimate includes a number of assumptions which are deliberately conservative. No allowance has been made for the radioactive decay which will take place before the Sr–90 descends from the stratosphere to the earth. This may diminish the amount of available Sr–90 by about 25 percent. The assumption that all of the Sr–90 in milk originated by root uptake, is another conservative assumption. It has been estimated that 30 percent of the Sr–90 in milk in 1956 originated by direct foliar deposition. The combined effect of these and other safety factors is apt to be appreciable.

A number of individuals have raised the question as to whether a discussion of average fallout values is adequate to define the upper limit of hazard to people exposed to unusually heavy fallout. In this connection it is worth noting that as the data continue to accumulate from every corner of the globe the large deviations from average are in the safe direction. Whereas fallout values greater than twice the mean are rarely reported in any given region, it is not uncommon to observe values which are of the order of 10 percent of the average.

This forecast has been made on the basis of data from Northeastern United States. How applicable are these data to other parts of the United States or of the world? Table 5 summarizes the concentration of Sr–90 in milk as observed in 6 domestic and 2 foreign sources of supply. These data, and the fallout measurements of figures 1 to 4 indicate that the Sr–90 content of dietary calcium might be higher in certain areas but a factor of 3 applied to the estimates for Northeastern United States should be adequate to bracket the highest foreseeable value, from tests to date, in any region of the United States.

II. Cumulative Gamma Dose Through June 1956

I would like to submit the attached table, "Cumulative gamma dose as estimated by gummed film measurements through June 1956." These data supplement the last report[1] from the Health and Safety Laboratory, which covered the period through September 1955.

It should be noted that these exposures are the theoretical exposures which would be delivered on the assumption that the measured fallout persisted indefinitely on the surface of an infinitely smooth plane. In actual practice the exposures would be very much less than the reported values due to various shielding factors as well as weathering. It is of course not possible to be quantitative about these factors in a general statement but most investigators would agree that the overall effect of these factors would be to limit the whole body exposure to less than 10 percent of the reported values.

Mr. EISENBUD. In this discussion I will describe the sampling program of the Atomic Energy Commission, and summarize for you the many useful conclusions that have been derived from analyses of the data.

The fundamental purposes of these studies are threefold:

1. How much strontium 90 has been deposited on the earth's surface?
2. How much strontium 90 from detonations to date remains suspended in the upper atmosphere, and how long will it take to precipitate?

How much strontium 90 will human skeletons contain when they are in equilibrium with the expected levels of strontium 90 in soil?

All of these subjects were discussed for you by specialists in meteorology, oceanography, and soil chemistry. Now that the theoretical background has been presented, I will present the data that have been obtained as a result of several years of study.

Samples are collected throughout the world for strontium 90 analyses. Most of these are sent to the United States for analyses, but others, in increasing numbers, are analyzed in the laboratories of other lands by many scientists whose data, like our own, are routinely submitted to the United Nations Committee on the Effects of Radiation.

Monitoring for radiostrontium can be divided conveniently into studies of its geophysical and biological distribution. Under the former classification are collected those samples which give us an understanding of the behavior of radiostrontium from its formation in the fireball to its deposition on the surface of the earth and incorporation into soils. The biological studies trace the movements of strontium 90 from the soils and waters through the flora and fauna of the oceans, pastures, and farms, to the skeleton of man.

Types of samples: For studies of the geophysical distribution of strontium 90, various kinds of samples are sought. A soil sample, expertly selected, can represent the accumulated fallout at a given location. An ideal sampling site is considered to be an open, level area, undisturbed by cultivation and covered by grass or simple vegetation to immobilize the surface. The most common division of sampling is to collect the top 2 inches and the 2- to 6-inch layer separately. The known area and the measured weight of sample allow the strontium 90

measurements to be converted to terms of millicuries per square mile.

Stainless-steel pots, with a face area of about 1 square foot, are finding increasing application in fallout sampling both here and abroad. The collected precipitation and dust are analyzed for strontium 90 at intervals, usually on a monthly basis.

The gummed-film collector was developed for a simple collecting technique suitable for network operations, where large numbers of collecting stations employ untrained personnel. This collector has an adhesive surface of 1 square foot which is exposed for 24 hours. A network of up to 200 stations collecting daily samples has been operated by the Health and Safety Laboratory of the Commission since 1951. Samples are mailed to the Laboratory where the analyses are performed.

Radioactive particulates suspended in the atmosphere can be studied by drawing a large volume of air through a filter. This type of sampling has been carried out at the earth's surface, in the lower atmosphere by aircraft, and in the stratosphere by balloons.

For studies of the biological distribution, the chemical similarity of strontium and calcium makes it desirable to use the strontium 90 to calcium ratio in tracing strontium 90 from soils to man. A useful unit, described to you yesterday, is the micromicrocurie of strontium 90 per gram of calcium.

The three principal types of samples taken for analysis are (1) vegetation, including both animal and human food, (2) milk, and (3) human bone.

The major source of body calcium in the United States is milk; hence its analysis has received considerably more attention than that of any other foodstuff, although other foods may have a higher strontium 90 to calcium ratio. Actually, cow's milk contains less strontium per gram of calcium than do the vegetables which comprise the balance of our calcium intake. This is because biological processes in general tend to discriminate against strontium. Thus the strontium 90 has been selectively eliminated by 2 stages—the vegetable and the cow—in the case of milk, and only 1 stage in the case of vegetable. Milk seems to be the most practical index of human exposure to strontium 90 because it is the source of most of the calcium in the skeletons of American adults, and it is a material which is relatively easy to sample.

Analyses of human bone afford a direct measure of the strontium 90 level at a given time. These samples show the lowest levels of strontium 90 of any biological material being analyzed. Since human bone is not yet in equilibrium with the strontium 90 of the environment, however, measurements made at the present time are only of value when viewed in relation to other materials, particularly human food and the present and predicted levels of strontium 90 on the earth's surface.

The subject of strontium 90 in human bones will be discussed in very great detail by Dr. Kulp, under whose capable direction these studies have been undertaken.

Estimates of fallout obtained by analyzing soil samples and gummed film are given in these charts. (See pp. 570, 571.)

I will explain for you, so you can compare the two, the data that have been collected throughout the world by two basic procedures that we use—gummed film and soil analysis.

You will note that in general the gummed film yields higher estimates of fallout than are actually observed by soil analysis. The reason for this is not clear, and remains to be investigated. But if we integrate the total amount of fallout on the surface of the earth, as prepared by the estimates from gummed film data, we come out with a total of about 1½ megacuries. That is, 1.5 million curies of strontium 90 are estimated from gummed films to be deposited on the surface of the earth; whereas in the case of soils we estimate about 0.8 million curies, 800,000 curies of strontium 90.

Thus, for some reason or other, which remains to be explained, the soil analyses yield about 59 or 60 percent of the values obtained from the gummed film, and for the purposes of discussion, I will use an intermediate value of 1 megacurie, which is in within 25 or 50 percent of either extreme.

Now, these charts are worth a considerable amount of study. One sees here the evidence of the latitudinal variation in results that was discussed by Dr. Machta yesterday and which has been noted in the publication of Dr. Libby. I want to caution you, though, that the difference is not a very large one, as we will see when I present the summaries of these data.

Particularly in the case of the soil samples one notices a path of higher fallout through the northern latitudes, with a corresponding diminution as one proceeds in a southerly direction. The same effect is also apparent in the case of gummed film, although the differences do not seem to be as great.

Mr. Chairman, you inquired yesterday as to whether we had any information about Japan, and I can submit data on the basis of both soil analyses and gummed films. We operate four gummed-film stations in Japan. These data indicate that the fallout in Japan is not higher than it is in other places in the northern latitudes, and, in fact, is considerably lower than in most parts of the United States.

Represent Holifield. In order to make the answer very clear—I do not believe your answer was as clear as I would like to have it on the record—have we used the same methods in testing the soil of Japan, and the same scientific methods in testing it there as we have in various parts of the world, including the United States? Have you used the gummed paper and chemical analysis of the soil?

Mr. Eisenbud. The analysis by means of gummed paper is the same as it is elsewhere in the world. We use one method for all samples.

Representative Holifield. You have not answered my question, and this is an important question because we do not want to convey to the people anything but the exact truth on this matter. We want to know if the same type of sampling was used on Japanese soil that is used on the American soil.

Mr. Eisenbud. Yes, sir.

Representative Holifield. So that the comparison is a valid comparison?

Mr. Eisenbud. Yes, sir.

Representative Holifield. Thank you.

Mr. Eisenbud. I want to add, along those lines, sir, that in recent months we have had confirmatory evidence from other governments. The Swedish Government, the British, the Canadians, the Japanese, perhaps 1 or 2 others, have submitted their own estimates derived

by methods which are similar but from analytical procedures in their own laboratories which indicate that, in general, we are in agreement.

Now, this chart (figs. 5 and 6) shows the latitudinal deposition. It is identified by the upper horizontal bars, which are the result of the soil samples, and the lower horizontal bars, which are the result of gummed-film data. (See p. 573.)

One notes, first of all, that the fallout in the United States is in fact very much higher than elsewhere in the world; secondly, that the North Temperate Zone does, in fact, show the stratification that Dr. Machta was talking about yesterday. But I would like to emphasize for the record, sir, that these differences are not large differences. They are differences that are going to require the resolution of fine shades of scientific opinions, but in terms of their practical significance I do not believe there is any difference between the interpretation that we have placed on these data in the past, and the way they are interpreted by some at the present time.

We have always known that the North Temperate Zone was higher than elsewhere in the world. In the past we attributed it to excessive tropospheric deposition. It appears now that perhaps the difference may be due to collective stratospheric deposition, but the fact is we knew it was there. So the evidence has come from these measurements, and not from theory.

Senator BRICKER. Doctor, how do you account for the fact there is a reversal of the testing in the United States, the soil testing showing a greater deposit than the gummed testing, and the reverse is true in the other testing?

Mr. EISENBUD. I do not know. The reason I was hesitating when Chairman Holifield asked his question before is there was a difference in the chemical procedures for these samples as compared with some of these [indicating], but this difference is at most 30 percent, and would not explain the complete reversal you see here.

Senator BRICKER. It is not as marked as that graph shows?

Mr. EISENBUD. I suppose this is the point in my presentation where we have to emphasize, as others have, that we have much to learn, and there are a great many things about these data that remain to be explained.

This, then, will summarize. How much is on the ground as of mid-1956?

I am going to use, for purposes of discussion, the round figure of 1 million megacuries of strontium 90, which is the intermediate of 0.88 estimated from soil analysis and 1.5 estimated from gummed film.

Senator BRICKER. If there were no more radiation activity put into the atmosphere at the present time, would the decay on the face of the earth offset the fallout that will continue for the years ahead?

Mr. EISENBUD. No, sir. I am going to come to that in some detail. That is a very important point, Senator. It is estimated in mid-1956 approximately 2.4 megacuries of strontium 90 were suspended in the stratosphere. The rate of precipitation of strontium 90 must also be considered in any estimation of future hazard. If the time of descent was infinitely great, the strontium 90 would decay before it reached the earth's surface, and would not constitute a potential hazard.

Actually, we have learned that the time of descent is relatively short in relation to the half life of strontium 90. It is estimated that the average residence time is approximatly 10 years—equivalent to a half

life of 7 years. It is possible this estimate is too long, and the average life may be as little as 6 to 7 years.

In any case, the bulk of the radioactive dust now stored in the stratosphere will have deposited by 1970. Thus essentially all of the 2.4 megacuries of strontium 90 stored in the atmosphere as of mid-1956 will be deposited on the earth's surface by about 1970.

This discussion will assume that the stratospheric fallout will be distributed in approximately the same pattern as in the past.

You see we do not have to hypothesize about the distribution in the stratosphere, because the pattern has been developed, and we will just assume that this, as Dr. Machta pointed out, will ultimately disclose what the stratospheric pattern is.

Now what, then, does the 1 megacurie on the ground plus the 2.4 that will be on the ground mean to man?

Our discussion of future levels of strontium 90 in man will be based on data for a region in Northeastern United States where the deposition of strontium 90 averaged 20 millicuries per square mile. Of this, about 6 millicuries per square mile is estimated to be tropospheric fallout from tests prior to mid-1956.

Another thing I want to point out, in fairness to all of you—is that Dr. Machta might disagree with this figure. I think instead of being 6, he might estimate as high as 8 or perhaps 10. But this would not affect the conclusion. My own estimate is 6 millicuries per square mile. In other words, 20 minus 6 equals 14 millicuries per square mile. This was the level which it is estimated that then existed.

It is estimated that when the 2.4 megacuries then in the stratosphere has deposited—I am talking about mid-1956—the deposition on this milkshed will be 45 millicuries per square mile, about 2.3 times the level in mid-1956.

To define the potential risk from a given distribution of strontium 90 on the surface of the earth requires that the distribution be quantitatively related to the skeletal burden of strontium 90 of a human population in dietary equilibrium with the soil from which its nourishment is derived. This equilibrium is already established for a variety of raidoactive elements normally present in the earth's crust.

For example, the average upper foot of soil in the United States contains about 1,000 millicuries of radium per square mile. The average adult skeleton in this country contains 10^{-4} microcuries of radium, resulting from assimilation of this trace element from foods and water. Thus the value of 10^{-4} microcuries of radium represents the amount deposited in the skeletons of the populations whose mineral metabolism is in equilibrium with the soil minerals.

Freshly deposited strontium 90 takes a relatively long time to complete the biological route to bone, since bone being formed at the present time utilizes calcium which left the soil in months gone by. In addition, storage of cattle fodder and holdup of human foods in commercial distribution lead one to expect the human strontium 90 burden to lag in time behind a given soil concentration. Equilibrium can be expected to be achieved over a period of years, but not over a period of months, or even a period of a few years.

During periods of actual fallout the concentration of strontium 90 in milk originates from the soil by normal root uptake as was discussed yesterday, or it may short-circuit the soil through deposition directly on the leaf and ingestion by the cow.

At present, the extent to which strontium 90 occurs in milk as a result of direct deposition on leaves is not known. This fraction presumably diminishes with time as the accumulation in soil increases and the rate of fallout remains approximately constant. In contrast, the strontium 90 of the soil constitutes a long-lived reservoir for the future uptake. Diminution will result only from radioactive decay or if the strontium 90 is leached beyond the root zone. For the purpose of this discussion it will be assumed that all of the strontium 90 in milk is metabolized by way of the roots. This is a conservative assumption which tends to exaggerate the forecast of future levels. Milk from the milkshed previously discussed has been sampled routinely since early 1954.

This pictogram gives the variation and the gradual increase of strontium 90 in micro-microcuries per gram of calcium in the milk of this large milkshed in the eastern United States.

There are a considerable number of details about which many interesting scientific discussions can take place, but the thing that is important is that the milk up until the end of December 1956 was gradually increasing, with some variations, which are presumably soil in origin, and which are becoming less important as time goes on.

Representative HOLIFIELD. Will you give us the percentage increase in that period? Was it 2 years or 3 years?

Mr. EISENBUD. It has gone from half a mirco-microcurie per gram of calcium to about 5. That is about a tenfold increase.

Senator ANDERSON. Do you expect that trend to continue?

Mr. EISENBUD. I am going to deal with this. It is a very important question. May I continue?

Representative HOLIFIELD. Yes.

Senator ANDERSON. I mean, if you do not expect it to continue, you give us the scientific basis why.

Mr. EISENBUD. I expect it to continue in a certain value. The next question I must answer, or attempt to answer, is what must this value be.

Representative HOLIFIELD. Do you believe you have an actual computation of the amount of fissionable material that has been released into the atmosphere from the three nations capable of testing these weapons?

Mr. EISENBUD. Yes, sir. It depends on how you define accuracy. There are areas in normal life, as well as in scientific work that where sometimes a factor of 10 is considered to be good enough. So you say a hundred thousand or a million, and you do not make any differentiation between them.

Obviously in this case, we want to do better than that. My own opinion is that we can estimate this within a factor of two, which I think, considering the levels that we are at at the present time, is sufficiently accurate to enable one to make a forecast of human hazards.

Representative HOLIFIELD. This would indicate, then, that you have confidence in your testing mechanism, whatever they may be, from the standpoint of the global testing?

Mr. EISENBUD. I have considerable degree of confidence, and personally have been very pleased by the amount of confirmatory evidence that has come in from investigators in this country and in other parts of the world that have tended to support the conclusions that we drew in a very preliminary way a year or 2 years ago.

Representative Holifield. Is it possible for you to extrapolate from air samples tested, let us say, over the United States, the power of the weapons which we have tested in the Pacific within any reasonable degree of accuracy?

Mr. Eisenbud. Well, sir, I am concerned in the analysis of the samples with the implication of health, and I am not attempting to diagnose weapons or estimate yields on the basis of the chemical work that is done. I think this is beyond my competence.

Representative Holifield. So you measure the amount of radioactivity in the air without any reference at all to the number or yield of weapons detonations which have taken place?

Mr. Eisenbud. That is right, sir.

Representative Holifield. You start with that fact?

Mr. Eisenbud. Yes.

Representative Holifield. I see.

Senator Anderson. Did you say something about these data being based on studies 2 years ago, or rather some conclusions being based on studies of a couple of years ago? You mentioned that just a moment ago.

Mr. Eisenbud. Yes, sir. I think in general, the model that has been developed has grown firmer with time, and has developed a considerably finer detail and greater internal consistency, if you will.

I think, unfortunately, many of the investigators, being very close to their particular specialty, have tended to emphasize differences in this fine detail, which do not really affect the conclusions one draws from the data.

Senator Anderson. I do not have your final statement. Have you referred to the National Academy of Sciences, or somebody, as having dealt with this matter?

Mr. Eisenbud. Yes, sir. That is a very fundamental part of the National Academy of Sciences study which was published last June and is still——

Senator Anderson. The study of the National Academy of Sciences was published last June?

Mr. Eisenbud. Yes, sir.

Senator Anderson. What data was that based on? What year? What period of time did it cover?

Mr. Eisenbud. They have access to data up through September 1955.

Senator Anderson. Did they have these figures showing a 10-percent increase?

Mr. Eisenbud. No, sir; these are about to be published now. But there is nothing surprising about these data. This is exactly in line with the forecast made about a year ago, and which I will cover later on in my prepared statement.

Senator Anderson. I am just reminded that I meant 10 times.

Mr. Eisenbud. Tenfold.

Senator Anderson. Tenfold, yes. The National Academy of Sciences is constantly quoted as saying there is no danger from radioactive fallout, and so forth. Did they look at this tenfold increase when they said that?

Mr. Eisenbud. When they saw the data it was not tenfold, but perhaps sevenfold, and the increase has been by the expected amount.

Senator ANDERSON. Has it been a curve that is moving upward, or is it a steady line?

Mr. EISENBUD. I think you are as good a judge of this as I am, sir.

Senator ANDERSON. It looks to me that if you plotted a curve, it might be moving upward very rapidly.

Mr. EISENBUD. It has got to reach a limit.

Let me get to this, if I may.

Senator ANDERSON. All right. Why does it have to reach a limit?

Mr. EISENBUD. Well, because there is just so much strontium, and when it is all accounted for there just cannot be any more from detonations to date.

Senator ANDERSON. But if it is accounted for by being deposited on the skin of the earth, it is quite a bit different from being buried somewhere, is it not? Never mind. I should know better than to start asking that type of question so soon.

Representative HOLIFIELD. Doctor, in making this statement, and bringing this chart to us, are you bringing to us information which has been approved and accepted as the Atomic Energy Commission's calculations, or is this your personal calculation? Are you doing it independently as a scientist?

Mr. EISENBUD. This is an independent calculation, but with the assistance of my colleagues and consultation with others within the Commission. We do not have the machinery within the Commission for producing a single so-called Commission computation.

There are a number of investigators within the Commission, and a great many more among the contractors of the Commission, all of whom are taking the same body of information and attempting to interpret it in their own way.

Representative HOLIFIELD. But the committee can understand that this is a statement approved by the Atomic Energy Commission?

Mr. EISENBUD. No, sir. I believe I am testifying in my individual capacity today, although——

Representative HOLIFIELD. That is the point I wanted to find out. That is fine.

Mr. EISENBUD. Yes, sir.

Senator ANDERSON. Just one minute. Are you not in the New York Operations Office of the Atomic Energy Commission?

Mr. EISENBUD. Yes, sir.

Senator ANDERSON. You are an employee of the Atomic Energy Commission?

Mr. EISENBUD. Yes, sir; but this is my statement. I am not reading a statement on behalf of anyone else.

Senator BRICKER. By that you mean that not all of the scientists in this field who are engaged in Atomic Energy Commission work would agree completely with you?

Mr. EISENBUD. I think they would agree with regard to the general conclusions. I think there would be a considerable measure of disagreement regarding details. But I think, as we hear about disagreement, we must ask ourselves, Does this disagreement really affect the conclusion?

Representative HOLIFIELD. Before we leave this part—and this is not to embarrass you, sir, but this is that the record may stand on its own feet, so to speak—you are presently on leave from the Atomic

Energy Commission, and you are acting as consultant to the United Nations?

Mr. EISENBUD. No, sir. I returned to active duty on Monday of this week. My 90 days with the United Nations were up.

Representative HOLIFIELD. You have been over the past certain period of time a consultant to the U. N. on this matter?

Mr. EISENBUD. No, not on this matter. I was senior scientific adviser to the Preparatory Commission drafting the program for the new agency.

Senator ANDERSON. Your name was on the agency payroll all the time; was it not?

Mr. EISENBUD. I was on the United Nations Preparatory Commission payroll for the 90 days, on leave from the Commission. That period expired on Monday of this week.

Representative HOLIFIELD. Thank you, Doctor.

Mr. EISENBUD. Now, the strontium 90 content of the milk from this milkshed averaged 3.5 micromicrocuries per gram of calcium in the period just preceding the sampling of the soils in October 1956 when the estimate of total fallout in this milkshed was made.

On this basis, then, we would expect this level of 3½ micromicrocuries per gram during this period to increase by a factor of 2.3 over the next months or years. So that the ultimate concentration in this milkshed will be 8.3 micromicrocuries per gram. I am sorry. It would be 8 micromicrocuries per gram. That will be ultimately somewhere about here [indicating], a little higher or a little lower. This is our best estimate at the present time.

Representative HOLIFIELD. That would be a factor of how many?

Mr. EISENBUD. 2.3 over this level in here [indicating]. This is our base—the average of these months.

Chairman DURHAM. That is based on the fact that all of it falls out?

Mr. EISENBUD. Yes, sir.

Representative HOLIFIELD. May I ask you why you use the 1955–56 level as a base rather than going back to 1954 as a base?

Mr. EISENBUD. We use this level as a base because this was the period when we were doing soil sampling in this milkshed, and what I want to do is relate the total amount on the ground, what is in the stratosphere, and this milk level during this period.

To show you this is a consistent pattern, sir, we did the same thing back here [indicating] a year ago in data which have been published. At that time we estimated that the maximum would be 8.3. So that 1 year has gone by, we have a lot of additional data, and we have revised our estimate from 8.3 to 8. Of course, there is no difference between the two.

When I say it is going to 8.3 or 8, this does not rule out the possibility that it may go to 10, but it certainly would not go to 80.

Based on the data now available, a child being nourished on milk containing 8 micromicrocuries of strontium 90 per gram of calcium would be expected to develop a skeleton containing strontium 90 in somewhat lower concentrations than this value, because the human metabolism discriminates in some measure against strontium.

Senator BRICKER. What is the relation of that discrimination to the amount of calcium that is in the milk? If there is more calcium in the milk is it a discrimination against strontium, greater or less?

Mr. EISENBUD. I am way out of my field now, but I think I can answer this competently. If the individual is on a calcium-deficient diet, then relatively more strontium would be taken up. But children who drink milk usually have a fairly large excess of calcium in their diet.

Senator BRICKER. The more calcium the less of the strontium that is assimilated?

Mr. EISENBUD. Yes—well, yes, sir. Based on data that have become available in human and animal experiments, a person on a diet of 8 micromicrocuries of strontium 90 per gram of calcium should develop a skeleton which has somewhere between 4 and 6 micromicrocuries per gram. So we start with a diet of 8, and it will drop to somewhere between 4 and 6. This seems to be the lower and upper limit.

Representative HOLIFIELD. Dr. Eisenbud, for the benefit of the lay readers who are not familiar with the term "millicuries," will you, or can you, in lay terms, express what this increased strontium 90 in milk means? When we talk about a tenfold increase in millicuries, this may be very alarming. Can we in some way express in layman's language this term so that the mothers, when they read this statement, will understand the significance of that measurement in relation to, let us say, a damaging amount? If you can draw any kind of comparison.

Mr. EISENBUD. I would prefer to leave the question of what level is damaging to the expert speakers who will come later on in the program, but I think that, for the purpose you have in mind, perhaps it would be worthwhile to point out that, when it is expressed simply as millicuries, which is a unit of activity, the natural radioactivity of milk, the radioactivity that has always been present not only in milk, but in other foods, is very much greater. It is my recollection that a quart of milk contains about, I think, a thousand disintegrations per minute. This is roughly 400 micromicrocuries. Now, a pound of beeksteak—again I am relying on my memory—has about 2,000 disintegrations per minute. That is almost a thousand micromicrocuries.

Senator ANDERSON. One time you use micromicro something else, and then you say "disintegrations." Can you keep it in pecks, quarts, or bushels?

Mr. EISENBUD. When we talk about the amount of strontium 90 on the earth's surface, we talk about millicuries, because we are talking about relatively large amounts.

Senator ANDERSON. Did you not start out to tell us what the natural amount of strontium 90 might be in milk, and then how much was added to it by these detonations? What is the relative ratio?

Mr. EISENBUD. The ratio of millicuries?

Senator ANDERSON. Well, whatever the unit of measurement is. In one study you found out it increased tenfold. What has happened in ordinary milk that you know about, against what might have come from strontium 90?

Mr. EISENBUD. All right. If you took a sample of milk before 1945, and put it in the Geiger counter, the background would go up because the milk always has a certain amount of radioactivity, just as all foods, rock, and tissue do. If you take a sample of milk now, and put it in the same Geiger counter, you cannot detect any difference. The difference is so small, against the background of radioactivity that is nor-

mally present, one cannot detect this strontium 90. You have to break it out chemically, and count it by low-level procedures after you have eliminated the natural radioactivity.

Senator ANDERSON. If it is so low that it is not measurable, is it at all dangerous?

Mr. EISENBUD. I think this gets us into a later section. For the record, and for orientation at this point, I can tell you that the maximum permissible exposure, or maximum permissible dose in human skeleton for public exposure, as recommended by various bodies that have considered this, is of the order of a hundred micromicrocuries per gram. One hundred.

Representative HOLIFIELD. How much do we have?

Mr. EISENBUD. Dr. Kulp later on this afternoon will no doubt tell you it is somewhat less than one. I am about to forecast how high it may go.

Representative HOLIFIELD. All right. Now let me ask you a question. In a normal calcium diet—I am going to refer this to children—in a normal calcium diet of a child, is it not true that most of the calcium is passed on through the body and is not retained?

Mr. EISENBUD. I understand that is so, sir.

Representative HOLIFIELD. In case there is strontium in that diet, mixed in that diet, is there a tendency for it to pass on through the body the same as calcium does? Or is there more of a tendency to retain it in the body than there is calcium?

Mr. EISENBUD. No, sir; it passes through like calcium. In fact, a little more of it passes through. That is why there is this discrimination. The human body prefers to take up calcium. Most of the time it cannot tell the difference between a strontium and a calcium atom, but sometimes it can. So, somewhere between 50 and 75 percent of the original ratio is retained, but, in general, it does pass through the body the same way as calcium does, and even a little more.

Representative HOLIFIELD. How does this compare to the natural radium that is in the milk?

Mr. EISENBUD. The uptake of radium is considerably less than the uptake of calcium.

Representative HOLIFIELD. Therefore, the retention of radium would be less, presumably, in the bone?

Mr. EISENBUD. Millicurie for millicurie, I would expect the uptake of radium to be less; yes, sir.

Representative HOLIFIELD. Then there is an affinity in the bone primarily for calcium, secondarily for strontium 90, and, in the third instance, for radium, in that order, you would say?

Mr. EISENBUD. Yes, sir. Others may correct me on this, but this is my opinion.

Senator BRICKER. Mr. Chairman?

Representative HOLIFIELD. Senator Bricker.

Senator BRICKER. Is there the same tendency on the part of plant-life in high calcium soils to reject the radioactive strontium as you find it in the human body?

Mr. EISENBUD. Yes. Really, I think that Dr. Alexander yesterday discussed this question in some detail, and pointed out that there was a discrimination in going from soil to plants, and then again within the body of the——

Senator BRICKER. Animal?

Mr. EISENBUD. Animal.

Senator BRICKER. And again, then, in the content of the milk there is a reduction, a natural reduction?

Mr. EISENBUD. Yes, sir.

Senator BRICKER. And then in the human body itself?

Mr. EISENBUD. Yes, sir.

Senator BRICKER. So you have four steps there, really, of discrimination against this alien element, you might say?

Mr. EISENBUD. Yes, sir.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Eisenbud, for the benefit of the record, can you give us, in plain words, the chemical structure of strontium 90?

Mr. EISENBUD. In the atmosphere it is usually as a silicate or carbonate, in the form of dust.

Representative VAN ZANDT. In the form of dust?

Mr. EISENBUD. Yes, sir.

Representative VAN ZANDT. Thank you.

Representative HOLIFIELD. Dr. Eisenbud, where is the milkshed you referred to, and how large is it?

Mr. EISENBUD. This is the milkshed located in the middle of New York State. The plant that processes this milk is located in western New York, and we regard these as representative of the New York milkshed.

In the full text of the report, sir, you will have tabulations of data like this for six milksheds in the United States and abroad, but I think you will find the numbers are in general agreement. For a while, one milkshed will get a little higher and then it will drop back to the others.

Senator ANDERSON. You said you were going to tell us what lies in the future.

Mr. EISENBUD. Yes, sir.

Senator ANDERSON. In order to make this a little topical, could you tell us for example from what you know of it, whether the British explosion that they had the other day—and I guess they are going to have more later on—how much of this strontium 90 it added which might deposit worldwide?

We had, finally, a little test yesterday, out in Nevada. Did it deposit strontium 90? In other words, are all of these things coming into the curve?

Many of us have been trying to point out that for a while only we were testing, then the Russians began to test, and apparently the Russians last year tested more than we did. Now the British are coming along. Pretty soon, of course, somebody else must come along. Do these add to it? And if so, how much.?

You are able to measure down to micromicrocuries. What do these add up to?

Mr. EISENBUD. When I have finished, I will have attempted to estimate how much strontium 90 is going to be in man from detonations to date. This covers a 6-year period. The only practical thing to do is to assume in the next 6 years the nations of the world are going to shoot as much as they have in the past 6 years.

Senator ANDERSON. Or tenfold, maybe.

Mr. EISENBUD. If we have the basic information, if we know what has happened up to now, we are in a position then to extrapolate. You can double it, or triple it, or stop entirely.

Senator ANDERSON. Here comes a brand new test by the British. Did it add some strontium 90?

Mr. EISENBUD. Yes, sir.

Senator ANDERSON. All right. It did?

Mr. EISENBUD. Yes.

Senator ANDERSON. That is good. How much did it add?

Mr. EISENBUD. We do not know. I do not know, sir.

Senator ANDERSON. Did you compute it on any basis?

Mr. EISENBUD. No. sir.

Senator ANDERSON. Was anybody curious about it?

Mr. EISENBUD. Yes, sir.

Senator ANDERSON. Did we not have—I do not want to get in the wrong field. Do we not have some way of measuring what was in it or estimating, let's say? Probably we had a way of measuring. Did we not have some way of finding out what was in it?

Mr. EISENBUD. If we have not done anything else, we will know about it when it comes down from the stratosphere.

Senator ANDERSON. I do not want to wait that long. I may die before it comes down. There is no way of estimating it now?

Mr. EISENBUD. Yes.

Senator ANDERSON. There is?

Mr. EISENBUD. Yes.

Senator ANDERSON. Is it impossible for you to give that to us? Is it secret?

Mr. EISENBUD. I do not have the information. You asked if it were possible to estimate. I said it is. That does not mean I can do it.

Senator ANDERSON. That is a completely honest answer. That is fine.

Mr. EISENBUD. All right.

Senator ANDERSON. How about the values—will we have some from the upcoming Plumbbob tests?

Mr. EISENBUD. Yes, sir; those tests will add to the fallout.

Senator ANDERSON. We have a bank account up in the sky sending down a little all the time, and then we keep adding to it, and disintegration is going on. Is anybody actually checking to see that the amount landing from previous accumulations and the amount that we are putting in now stays in balance with the decay?

Mr. EISENBUD. Yes, sir. We have enough information now, and large enough machinery so that now for the first time it is possible to predict what the fallout traces is going to be 2 years from now, 5 years from now.

Senator ANDERSON. I missed some of the previous testimony. Was it pointed out there is this difference, this heavy deposit in Wales, for example? And will that pattern be repeated around the world?

Mr. EISENBUD. The abnormality of deposits in Wales was not one due to the heavy deposits.

Senator ANDERSON. What was it due to?

Mr. EISENBUD. Dr. Alexander, who testified yesterday, went on a search around the world for an area in which the soil was conspicuously low in calcium, yet sufficiently fertile for at least sheep raising; and he

found this area in Wales. It is agriculturally a very unimportant area, but scientifically a very interesting one. He brought soil and bone back, and analyzed it, and the sheep bone had more strontium 90 than usual because of the low level of soil calcium.

Senator ANDERSON. That is what was found out about the human body: If there is a calcium deficiency, the greater the affinity for strontium; and if a calcium deficiency in soil, the affinity for strontium is greater.

Mr. EISENBUD. I think Dr. Kulp will deny that.

Senator ANDERSON. He will?

Mr. EISENBUD. He is going to testify.

Senator ANDERSON. All right.

Senator BRICKER. Just one more inquiry for the purpose of the record. I think there was testimony here a day or two ago, that the abnormal amount, not the abnormal amount, but the additional amount of strontium deposit in Washington at the time of the rain after the drought, was caused by the Russian tests. You would confirm that?

Mr. EISENBUD. I cannot confirm it, sir. We attempted to confirm it, and so far we have failed to do so. But it is a little early. It is a matter of a month or 2 months for the data to catch up with it. As of now, I cannot confirm it. The little bit of looking at it we have done—we do not have the data, but it is not surprising, I do not think, that from time to time there will be relatively heavy fallout here.

Representative HOLIFIELD. Dr. Eisenbud, I am going to ask you another question along the lines of the first ones I asked you. I do not want to oversimplify this matter, but first I am going to ask you: Do you have children?

Mr. EISENBUD. Yes, sir.

Representative HOLIFIELD. Now I am going to ask you if you would have any hesitancy at all in allowing your children to drink milk which has been produced on this milkshed?

Mr. EISENBUD. No, sir.

Representative HOLIFIELD. The reason I asked you that is because I want a plain understandable answer of your evaluation of the hazard that is involved, because when we are talking in tenfold increases of micromicrocuries, we are talking in a term which the average mother does not understand. But I think she could understand the fact that you, as a scientist, on your integrity as a scientist, would say that you would have no hesitancy in giving milk from this milkshed in any quantities that the child might want to your own children.

Mr. EISENBUD. None at all, sir.

Representative PRICE. Mr. Chairman, may I ask a question?

Representative HOLIFIELD. Mr. Price.

Representative PRICE. Dr. Eisenbud, does cesium 137 also show up in milk?

Mr. EISENBUD. Yes, sir. If I may defer this to Dr. Langham, who is going to testify later on this morning, I would like to do so.

Representative PRICE. Thank you.

Mr. EISENBUD. Let us use as a basis for discussion the 5 micromicrocuries of strontium 90 per gram of calcium, which we predict may be the maximum in perhaps 1970 or so. One can calculate that this amount of strontium 90 will deliver a dose of half a roentgen to the skeleton over a lifetime of 70 years. This compares with a normal skeletal irradiation—I want to repeat this for the record, sir: This

compares with a normal skeleton irradiation of 7 to 30 rads. So, I am comparing half a rad to somewhere between 7 and 30 rads resulting from potassium 40, carbon 14, cosmic rays, terrestrial gamma radiation, and radium. They are the natural radioactive constituents of our environment, to which man has been exposed throughout his development.

Senator BRICKER. That is the background radiation?

Mr. EISENBUD. Yes, sir. That is, the maximum foreseeable value of 5 micromicrocuries of strontium 90 per gram is equivalent to 1½ to 6 percent of the dose from natural sources of skeletal irradiation. It should be noted that this estimate includes a number of assumptions which are deliberately conservative. No allowance has been made for radioactive decay before the strontium 90 descends from the stratosphere. This may diminish the amount of available strontium 90 by about 25 percent. The assumption that all of the strontium 90 in milk originated by root uptake is another conservative assumption. The combined effect of these and other safety factors is apt to be appreciable.

The question has been raised as to whether a discussion of average fallout values is adequate to define the upper limit of hazard to people exposed to unusually heavy fallout. In this connection, the deviations from average are in the safe direction. This was brought out yesterday, independently, by Dr. Machta. Whereas fallout values greater than twice the mean are rarely reported in any given region, it is not uncommon to observe values which are of the order of 10 percent of the average. This forecast has been made on the basis of data from Northeastern United States. How applicable are these data to other parts of the United States or of the world?

Summaries of the concentration of strontium 90 in milk as observed in 6 domestic and 2 foreign sources of supply, as well as the data from the fallout measuring systems described earlier, indicate that the strontium 90 content of dietary calcium might be higher in certain areas. However, a factor of three applied to the estimates for Northeastern United States should be adequate to bracket the highest foreseeable value, from tests to date in any region of the world.

Thank you, Mr. Chairman.

Representative HOLIFIELD. Thank you Mr. Eisenbud.

Are there any further questions of the members?

Are there any questions from the staff?

Chairman DURHAM. Mr. Chairman.

Representative HOLIFIELD. As I have said before, we are reserving the right to study the statements that are presented, and then it is possible there will be further discussion on it during the hearings, or there will be letters addressed to those giving the presentations for answers to certain questions which may come up as a result of the analysis of the statement.

Mr. Durham.

Chairman DURHAM. No questions now.

Senator BRICKER. One question, Mr. Chairman.

Representative HOLIFIELD. Senator Bricker.

Senator BRICKER. It is your professional opinion, as an expert in this field, that we have reached a point of no danger, and you do not anticipate any danger point as far as the future is concerned?

Mr. EISENBUD. What I have described for you is the situation that I see on the basis of detonations to date. Now, if I predict 5 micromicrocuries per gram, it is very simple arithmetic to say how many times you would have to increase the rate of firing in order to get up to what we agree is a dangerous level. This would be a very considerable amount, and, at the present rate of testing, I personally am not apprehensive as to the long-range hazards.

Senator ANDERSON. You had a curve in there, it seemed to me, showing how this amount had increased, and it might again increase. If you also had a curve of testings, you would have an additional factor to take into consideration. We had a test several years ago out in the far Pacific, and then went for a long time without another one. Now, the Russians have 1 every 2 weeks, and we are scheduled to have maybe 2 a week here for a while. The British have started coming in. If you would plot all of these tests onto a curve, it would be moving up rapidly, and, with the amount of strontium 90 coming down out of the atmosphere also moving up rapidly, the two of them might change the figures a little, might they not?

You have projected these figures on the present rate of testing. It is like predicting the number of automobiles that would move if they all stayed at 10 miles an hour. They did not. They speeded them up. They got very much faster. Now the speedup on tests is very much faster, is it not?

Mr. EISENBUD. These calculations are, as you are aware based on testing up to late 1956, and there has been nothing in the testing schedule of the past year which would drastically alter these conclusions.

Senator ANDERSON. Wait a minute, now. I am just wondering I think I went out to the very first test in the Nevada proving grounds. We did not have too many test devices. Would not the amount of strontium 90 have some relationship to the number of devices tested?

Mr. EISENBUD. It has a relationship to the devices tested, and certainly the number of devices is part of the overall picture. Yes.

Senator ANDERSON. Yes; very, very substantially, because, if we make use of certain types of weapons, the strontium 90 fallout would not be proportionate to the power of the weapon at all. It is the devices that are somewhat smaller, maybe, that they have in development. So, would it not be important to chart the number of actual devices shot off in the plub-bob tests which will have many more than some of the earlier tests?

Mr. EISENBUD. I think it goes without saying, sir, that the basic purpose of these studies is to point out how many bombs you can detonate.

Senator ANDERSON. For the purpose of finding out, you say this line is moving up. We now proceed to freeze it at a level. But, with new countries coming in, with the multiplicity of our own shots, the tremendous multiplicity of the Russians, it is not going to stay level; it is going to go up with tremendous speed, apparently, in the future. What does that mean, biologically? That is one of the problems you have to consider.

Mr. EISENBUD. Yes, sir.

Senator ANDERSON. That is all.

Representative HOLIFIELD. The staff informs me you had two charts, one showing the Northern Hemisphere, and the other the Southern

Hemisphere, the radioactivity. Had you intended to produce them?

Mr. EISENBUD. We must be mixed up. I thought I did. This [indicating] shows for the soil samples and the gummed-film samples the latitudinal differences that exist.

I pointed out that the United States has in fact relatively heavy fallout in relation to other regions of the world. While this increase in the North Temperate Zone is obvious and has been known to us for some time, it is a difference of about, say, a small factor from the north Tropics, and very——

Representative HOLIFIELD. The chart does show that the latitude-longitude in which the United States is located is receiving, I would say, all the way from as much as five times the south Tropics to double the North Temperate?

Mr. EISENBUD. Yes.

Chairman DURHAM. Prior to 1945, was the amount of strontium actually known at that time?

Mr. EISENBUD. It did not exist, sir.

Chairman DURHAM. It did not exist?

Mr. EISENBUD. No.

Representative HOLIFIELD. Thank you very much, Mr. Eisenbud.

I will insert in the record at this point a study entitled "Summary of Analytical Results from the HASL Strontium Program, July-December 1956" by John H. Harley, Edward P. Hardy, Jr., Ira B. Whitney, and Merril Eisenbud.

(The study referred to follows:)

UNITED STATES ATOMIC ENERGY COMMISSION,
NEW YORK OPERATIONS OFFICE,
HEALTH AND SAFETY LABORATORY,
March 15, 1957.

SUMMARY OF ANALYTICAL RESULTS FROM THE HASL STRONTIUM PROGRAM JULY THROUGH DECEMBER, 1956

By John H. Harley, Edward P. Hardy, Jr., Ira B. Whitney, and Merril Eisenbud

ACKNOWLEDGMENTS

1. To Dr. Lyle T. Alexander, Chief, Soil Survey Laboratory, United States Department of Agriculture, for collecting and arranging for many of the samples reported here.
2. To the members of the Analytical Branch staff who performed most of the analyses reported, particularly Charles F. Baxter, Ira Cohen, William R. Collins, Jr., Gerald H. Hamada, Helen W. Keller, John J. Kelly, Americo Rodriguez, and Bernard Stern.
3. To Isotopes, Inc., and Nuclear Science & Engineering Corp., who performed certain analyses under contract to the Atomic Energy Commission. Such results are marked "(I)" and "(N)" in the tables of data.
4. To Mr. Eric W. Mood of the New Haven Department of Health for supplying dustfall samples collected by his organization.

This report summarizes the data on samples collected for the HASL strontium program during the period—July through December of 1956. Previous data was given in NYO-4751 (revised).

In addition to the analysis of samples collected for the HASL program, the Analytical Branch is responsible for the transmittal of samples to contract laboratories. These samples are part of the overall strontium program of the Division of Biology and Medicine. This activity, including preliminary treatment of certain samples, calculations and administration require the equivalent of one full-time man. Direct analyses and administration require 2 staff members for the gummed film program and 8 for the strontium program.

FALLOUT DOCUMENTATION

Gummed film network

Through the cooperation of the United States Weather Bureau and other groups, daily gummed film samples are collected at 40 stations within the continental United States and 75 stations in United States Territories and in other countries. Results through September 1955 have been reported previously.[1] The current data carries through September 1956.

Measurements are made by beta counting of ashed samples. Strontium 90 estimates are made by theoretical calculations, assuming a date of origin for the debris. The results are mapped in figure 1 for the United States, and figure 2 for the rest of the world.

In previous reports it was described how a factor of 1.6 was required to correct gummed film mixed fission product activity to agree with pot samples collected as HASL. This correction has been applied to gummed film results issued since that time for all stations.

Several groups of results in this report would indicate that a much larger correction factor would be in order, but this is not necessarily true. It is believed that the low strontium 90 values calculated from gummed film activity are due to the incorrect arbitrary burst assignments used in the calculations.

The recalculations of the gummed film values will be done, but it will be some time before the results are available. Therefore, gummed film data in this report, particularly after May 1956, should be considered as minimum estimates, and may be low by a considerable factor.

United States soil program

The advantages and disadvantages of gummed film for fallout measurement have been discussed many times previously. One possible calibration is the comparison of cumulative gummed film results with analyses of soils taken at identical locations. The first such collection was undertaken at 17 Weather Bureau stations in October 1955 and was repeated in October 1956. In both cases, 0–2 inch and 2–6 inch depths were taken, and strontium 90 leached with 6N HCl.

The 0–2 inch depths for the 1955 samples were reported in NYO–4751.[2] The 2–6 inch depths gave the analysts considerable difficulty due to interference from thorium chain isotopes and they were not reported. A procedure has been worked out for these soils and those having residual sample available will be reanalyzed.

The data for the 1956 samples is shown in table 1 and a plot of soil activity against the values estimated from the gummed film is shown in figure 3. As in the 1955 data, Albuquerque, Grand Junction, and Salt Lake City show lower soil values than predicted. The mean ratio of soil/film is 2.33 for the 14 "normal" samples. (Gummed film values already multiplied by 1.6 correction factor.)

If the 1955 samples are corrected to total mc./mi.^{2} using the 1956 ratio for total to topsoil activity, the mean ratio becomes 2.4. The value of 1.6 reported in NYO–4751 was for the 0–2 inch depths only.

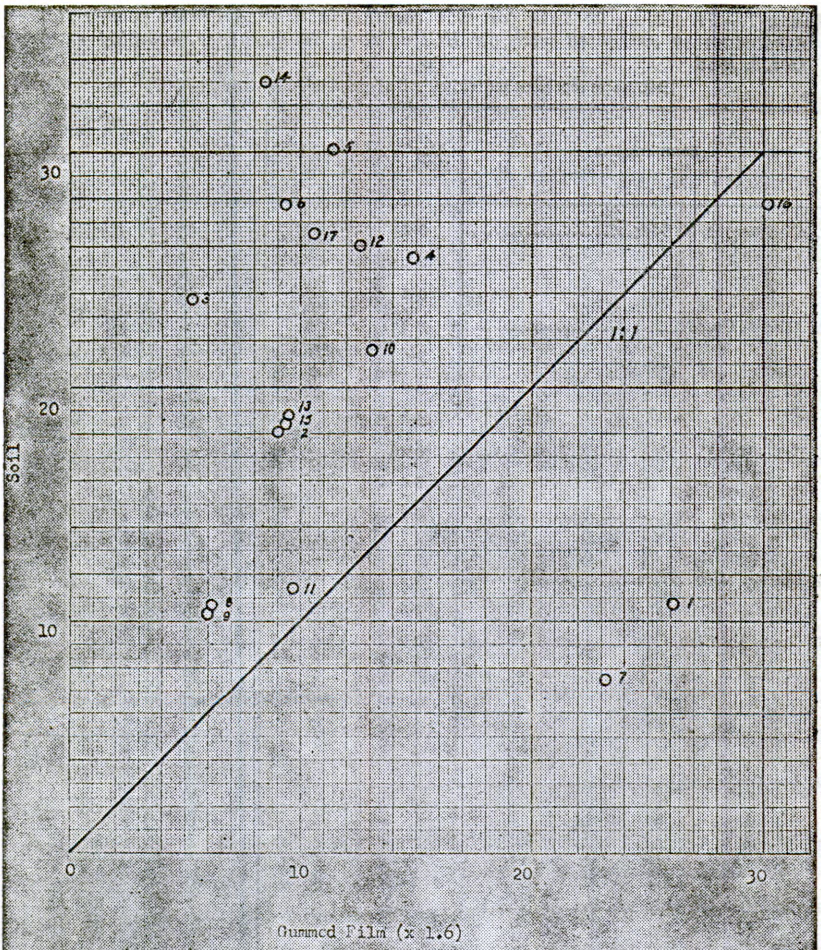

Fig. 3

Soil - Gummed Film Relationship for Sr-90 (mc/mi^2)

Further investigations are in progress on the reasons for the deviations shown by the three stations mentioned above. In addition, analysis of foreign soils will be made where available to extend the comparison.

Other comparison programs

Other sampling procedures for fallout documentation are by collection in a high-walled pot, or by collection of rainfall. These procedures may also be used for calibration of the gummed film. The first is represented by data from New York City by HASL, and the second by data from Pittsburgh by Nuclear Science & Engineering Corp. under AEC contracts. The detailed data will be presented later, but table 2 indicates the cumulative results useful for calibration purposes. For comparison, the New York City (La Guardia Airport) soil and gummed film data are included.

The pot and rainfall samples show that the 1.6 correction factor is not sufficient for this period. It must be emphasized, however, that this is not necessarily a failure of the original pot to film calibration figure of 1.6. It is more likely a failure to attribute measured MFP activity correctly to earlier tests, with a corresponding error in strontium-90 estimation.

TABLE 2.—*Gummed film comparisons (cumulative mc/mi²)*

	October 1955	October 1956	Δ	Ratio
LaGuardia:				
Soil	13.0	26.0	13.0	
Gummed film	2.6	7.9	5.3	2.45
HASL:				
Pot	14.9	25.9	11.0	
Gummed film	3.8	9.3	5.5	2.0
Pittsburgh:				
Rain	6.5	16.2	9.7	
Gummed film	2.6	8.5	5.9	1.65

NOTE.—Gummed film values not corrected for efficiency.

New Haven dustfall

The bureau of environmental sanitation of the New Haven Department of Health collects monthly dustfall samples at several stations in and around the city. The collectors are standard 1,500 ml. beakers, and duplicate samples are analyzed for dust content, one by evaporation of any rainfall and the other by filtration. The samples supplied to HASL were measured for total MFP activity and Sr–90, and the results are shown in table 3.

While the data are not as complete as desired, there are several interesting points:

1. Filtration or evaporation are equally effective for dustfall by weight.
2. Filtration loses both MFP and Sr–90 by solubility.
3. The agreement in activity values between stations is fairly good, and is independent of the dustfall.

A comparison of the mean Sr–90 values from the evaporated samples and the corresponding gummed film estimates (New Haven Airport) is shown in table 4. It appears that the gummed film activity should have been attributed to an early test series, rather than current tests, to give better agreement.

Current pot program

The uncertainty as to the source of current fallout requires more extensive calibration than in the past. The simplicity of gumed film for daily network operation makes it necessary that it be retained for routine sampling. The possible errors in attributing activity to a given source is expected to be overcome by a broader network of pot-sampling stations. The operating and projected stations is the HASL program are shown in figure 4. These samples will be collected monthly and analyzed for MFP and Sr–90 and probably for Cs–137.

Cooperative tests will start in April 1957 on a fallout collector designed by Dr. Bo Aler, or Sweden. Fallout collects in a plastic funnel and is passed through a filter and ion-exchange column to collect the activity. Such a collector would be simple to maintain and to ship to a central laboratory for processing.

Summary

The sets of data on fallout from the United States soils, the New Haven dustfall, and the pot and rainfall from New York City and Pittsburgh all indicate that the current gummed-film estimates of Sr–90 deposition are in error. This is particularly true for activity attributed to tests in the summer of 1956. The actual Sr–90 measurements show the debris to be much older, and the gummed film data must be recalculated on this basis.

It was not possible to recalculate the mass of data involved for this report, but this will be done. In the meantime, the gummed-film estimates of Sr–90 must be considered as minimum values, subject to correction.

Futher samples and analyses on pot and soil samples are required before conclusions can be drawn as to the extent and uniformity of fallout outside the United States. Such work is in progress and will be reported when the results are completed.

PASTURE PROGRAM

Not all of the 1956 samples for the HASL pasture program have been received, and no Sr–90 data will be reported until all analyses are complete.

There have been several improvements in analytical techniques since the 1953 and 1954 pasture samples were run originally. Therefore, all samples still available will be reanalyzed in the coming months. When complete, the 4 years data will be reported as a unit.

One approach to estimating the eventual equilibrium state of Sr–90 in the biological cycle is through measurement of stable strontium and calcium. Some of the original pasture samples have been run for stable strontium and are reported in preliminary form in table 5. No attempt at interpretation will be made until further analyses are completed. (See also section on milk analyses.)

NEW YORK CITY MONITORING PROGRAM

Pot sampling

A high-walled stainless steel pot is maintained on the roof of HASL for fallout sampling. The results of weekly collections are given in table 6 and the cumulative curve is shown in figure 5.

It was found that agreement between duplicate pots is not good. This is mostly caused by the low activity levels. Such deviations are expected to be reduced by exposure for 1-month periods and by counting on lower background equipment. The latter is shown partially by the data after September 24, 1956, but further improvement will be possible as more counting equipment will allow longer counting times.

Tapwater

New York City tapwater has been analyzed since August 1954. The results obtained since issuance of NYO–4751 are given in table 7. The weighted average value for the 6-month period is 0.19 μc/liter.

Milk

The results of milk analyses performed since the issuance of NYO-4751 are given in table 8 and the continuous curve for dried milk is shown in figure 6.

The level increased during the summer of 1956 and has maintained its level after the normal pasture season. This probably indicates that the cows are feeding on vegetation exposed during the summer and will stay at the same level until the next pasture season.

In NYO-4751, some concern was shown that wet milk purchased in New York City showed higher levels than the dried milk being analyzed. This is apparently due to the difference in source area of the two supplies. As a check, however, Dr. Alexander obtained wet milk, dried milk, and the washings from the drier during a run at Columbus, Wis. These samples are being analyzed to check possible loss of strontium 90 during processing and to test uniformity of run.

Wet milk samples were not run during this reporting period, but a more extensive sampling program for the city supply was started at the first of 1957.

Some of the dried milk samples have been analyzed for stable strontium. The preliminary data are given in table 9.

Tests have shown that dry ashing of milk results in loss of cesium 137, even at low temperatures. No cesium 137 results on milk will be reported until improved techniques are available.

Urine

Urine samples from laboratory personnel and others in the city have been run at intervals. The values found for Sr–90 and Cs–137 are given in table 10. The period of sampling is too short to indicate any trend.

OTHER MONITORING

Milk supplies

Dried milk from several sources in the United States and abroad has been analyzed. A complete summary of the data is given in table 11.

The high value for Mandan led to analysis of soil and animal bone for this region. The bone ran 24 $\mu\mu$c/g. Ca and the soil 6.4 $\mu\mu$c/g. Ca with 10 mc/mi.[2] Neither the fallout nor the activity relative to calcium is high for the soil, yet the bone value is what might be expected from the high level in the milk. The milk samples from other sites are reasonably close to the level found for New York.

Fish samples

Canned tuna of known origin plun canned Alaska salmon and bonito are analyzed on a regular basis. The results of all analyses to date are given in table 12. There are no apparent trends.

Pittsburgh rain collection

Rainfall has been collected since February 25, 1955, at Pittsburgh. The collections are made by Nuclear Science and Engineering Corp. with a pair of tubs having a total area of 5.16 square feet. The collection periods are of irregular length and the analyses are performed at NSE. The cumulative data are shown in Figure 7.

The accumulation of Sr–90 at Pittsburgh is in reasonable agreement with the results obtained at HASL. At the end of 1956, Pittsburgh showed 17 mc/mi.[2], while HASL showed 18 for the same period.

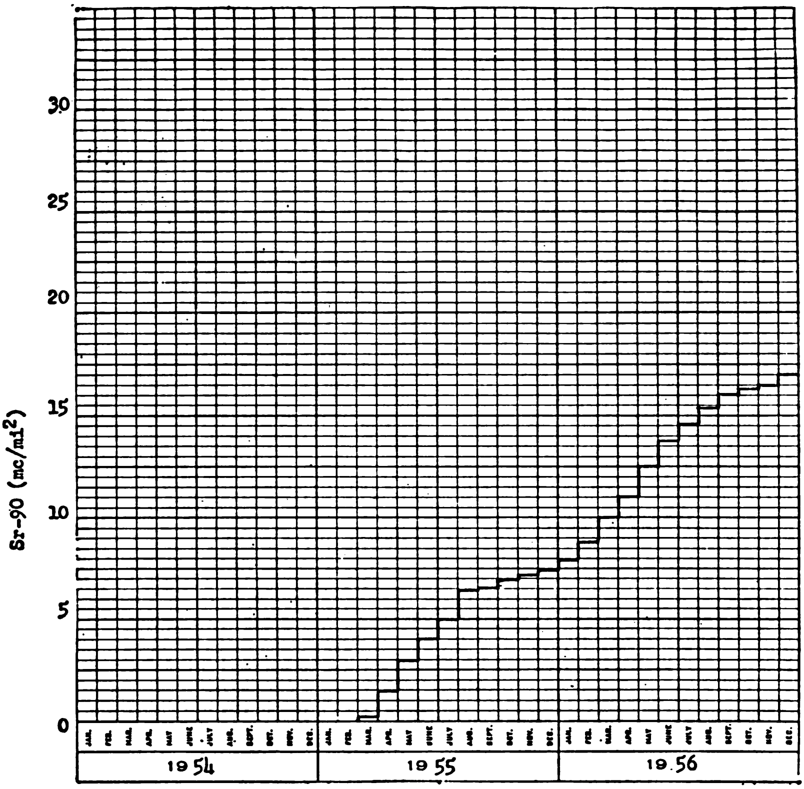

FIGURE 7.—Cumulative Sr–90 from rainfall collections at Pittsburgh.

BEAN EXPERIMENT

During the summer of 1956, three plants, snap beans, lima beans, and black-eyed peas were grown at the Beltsville Laboratory of the United States Department of Agriculture. The leaf, stalk, pod, and fruit of each were analyzed separately and the snap bean and black-eyed pea samples were run in duplicate. The results on the plants are given in table 13, while the soil analysis is shown in table 14.

Normalizing the data to stalk=1, the mean strontium unit values for leaf, fruit, and pod become 0.85, 0.52, and 0.54, respectively. The mean Sr–89/Sr–90 ratios are 1.9, 0.2, 0.7, and 1.4 for the leaf, fruit, stalk, and pod. While such averaging may not be completely justified, it would lead to the following conclusions:

1. The high stalk activity may indicate uptake that is partially blocked from the rest of the plant.
2. The leaves show higher strontium unit values than the pod and fruit, indicating some leaf retention.
3. The Sr–89 values indicate that the leaf and pod activity is younger than the fruit activity.

It is also of interest to note that the Sr–89 values indicate that some of the topsoil activity is younger than the bottom fraction.

LABORATORY PROGRAM

Several phases of Analytical Branch operations other than direct analyses are related to the strontium program. Progress on these projects is reported here for completeness.

Wisconsin milk experiment

Dr. Alexander collected samples during a milk drying run at Columbus, Wis., on November 13, 1956. Dried milk was taken at the start of the 16-hour run, and every hour to the end. Whole milk from the start and end and caustic washes from the cleanup were also taken.

Since processing consumes about 1 tank per hour and 1 tank represents the largest blend made, the test should indicate the variability that might be expected in Sr–90 and Cs–137 for a normal run. Since our normal sampling is a 5-pound can selected weekly, this variability will be extremely important.

Cs–137 analysis

Analysis of certain samples for Cs–137 will help in understanding parts of the strontium program, as well as having value in themselves.

The estimation of gamma dose from fallout will rely heavily on Cs–137 determinations for old debris. The gummed film is adequate for evaluating fresh activity, but analysis of pot samples for Cs-137 will assist in assigning an age to the material. The concentration of Cs–137 in foods and in human urine will be of direct interest.

The analytical methods are satisfactory for all types of sample except milk. There is considerable loss of cesium in the dry ashing process, even at 500° C. Still lower temperatures and a wet ashing process are being evaluated.

Laboratory manual

The methods for analysis of Sr–90, Sr–89, Cs–137, calcium, strontium, and mixed fission products are included in the Analytical Branch laboratory manual, which is being issued in looseleaf form as NYO–4700.

Standard samples

Standard samples are being prepared to assist laboratories starting work on strontium analysis. These are:

1. Milk ash
2. Bone ash (animal)
3. Bone ash (simulated human)
4. Bone ash (blank $Ca_3(PO_4)_2$)
5. Vegetation ash (hay)
6. Mixed fission products (for separation studies)
7. Soil
8. Standard Sr–90—Y–90 solution in ampoules (100 d/m)

Samples 1, 3, and 4 are being analyzed at 3 or 4 laboratories. Samples 2, 6, and 8 are in preparation. These samples will be forwarded to any laboratory, on request, with a statement of Sr–90 and calcium content. From 200 to 500 bottles of each sample will be available, each one adequate for duplicate or triplicate analyses.

Soil comparison

Dr. Alexander, of the Department of Agriculture, is preparing large samples of soil for determination of Sr–90 and calcium by several methods. These will assist in evaluation and selection of the best available methods of analysis. Previous comparisons have been limited in scope, but have shown large deviations between methods, and one broad experiment is now required.

Intercomparison report

A summary of all laboratory intercomparisons on all samples run to date has been completed, and will be issued as an NYO report. Agreement between laboratories is generally good, but there are enough major variations to warn against placing reliance on single results.

Control milk

The Analytical Branch has been running an analysis monthly on large batches of dried milk. The first lot, run from June of 1954 through April of 1955, showed values of 0.91 ± 0.11 $\mu\mu c/g$ Ca for 10 analyses. The second lot, run from August

of 1956 through December of 1956, showed values of 4.6 ± 0.7 $\mu\mu c/g$ Ca for 16 analyses. Although there are insufficient data for a complete statistical analysis, the results indicate some deviations greater than expected from counting error. Future control samples will be ashed and blended before use to remove the variation between cans in the same lot.

Representative HOLIFIELD. Before we proceed with our next witness, I have several statements I would like to insert in the record. The first is by Dr. W. F. Libby, a Commissioner of the Atomic Energy Commission, then a statement and a report by Dr. E. A. Martell, of the Air Force Cambridge Research Center, and finally a statement from the Naval Research Laboratory.

(The statements referred to follow:)

STATEMENT BY W. F. LIBBY

TOPIC IX

I would like to submit seven charts for the record.

Chart 1 shows "collectioln pot data for Pittsburgh." This is sometimes referred to as rainfall data. A washtub or similar container is placed at a carefully selected site and the material which falls into it (dust, soot, rain, etc.) is collected periodically and analyzed for strontium 90. It is a differential method since it gives the amount of strontium 90 that has been deposited in the interval between collections.

The curve on the chart is a cumulative one, since the strontium 90 reported for each sample collected from the tub is added to the total of all the previous reports. Thus, a steadily rising curve is obtained, which at any time gives the total of strontium 90 that has been collected at that site.

At the bottom of the chart are indicated the announced dates of detonations by the United States, United Kingdom and U.S.S.R. Dots indicate whether the detonations were air burst or surface burst, if that information is available.

Chart 2 is similar to chart 1, but the data are those for New York City. In the case of the New York data, we have, on occasion, obtained and analyzed samples of soil and found them in good agreement with the strontium 90 levels estimated from this curve.

Chart 3 is another way of presenting collection pot data. In this chart we have plotted each month's accumulation individually without adding it to the previous month, so that on this plot the individual points represent the monthly rate of fallout. We have included the first few results from the worldwide network of collection pot stations which we are in the process of establishing. In general, there has been a station in the gummed film network for some years at these same sites.

Chart 4 is a plot of the strontium 90 content of some soil samples taken in Asia Minor in 1955 from the annual rainfall at those same sites. This chart shows a very interesting relationship between the amount of rain and the amount of fallout.

Chart 5 is a spot map of the United States in which we have indicated the strontium 90 content of the soil in October 1956. These soil samples were obtained and analyzed in a cooperative venture of the AEC Health and Safety Laboratory and the United States Weather Bureau.

Chart 6 is similar to chart 5; however, we have used the collection pot data of charts 1 and 2 to estimate the increment of fallout between October 1956 and April 1957. Thus, we have been able to estimate the probable soil values at these same stations for April 1957.

Chart 7 is similar to chart 1. The data are those for Chicago for the years 1953–55 and are the data collected while the method was being worked out and checked. Note the agreement between the two soil samples and the rainfall curves.

I-B. UNPUBLISHED, UNCLASSIFIED FALLOUT DATA

Analysis of strontium 90 in Antarctica snow cores, collected early in 1956, are in progress. Results should assist in establishing deposition rate and total deposit of delayed fallout in Antarctica. Partial results can be submitted to the Joint Committee on Atomic Energy by letter report upon request.

II. INTERPRETATION OF GEOPHYSICAL ASPECTS OF DELAYED FALLOUT

Present stratospheric burden of strontium 90 and other long-lived fission products can be only crudely estimated in view of the large uncertainties in the amounts introduced and in the rate of removal. However, Dr. W. F. Libby's estimates of 2.4 megacuries of strontium 90 as the total stratospheric burden in June 1954 and again in June 1956 are undoubtedly good approximations.

The rate and extent of stratospheric mixing are unknown. Thus the present and subsequent vertical and lateral distribution of stratospheric fission product debris are uncertain. The United States Atomic Energy Commission balloon sampling program which has been in progress over the last half year should provide information on the distribution.

The mechanism of transport of stratospheric debris into the lower atmosphere is not clearly understood. Thus the path and rate of deposition of delayed fallout cannot be described with confidence at the present time. Proposed mechanisms include slow worldwide mixing through the tropopause and, alternatively, entrainment of stratospheric debris into the jet stream. Differences in tropopause definition and jet stream activity for the Northern and Southern Hemispheres may lead to differences in consequent ground distribution in the two hemispheres. If jet stream entrainment were the dominant mechanism in the Northern Hemisphere it would result in higher deposition in the middle latitudes, a result not inconsistent with observed ground levels.

Rainfall scavenging is clearly the dominant mechanism which controls the deposition of delayed fallout once it has mixed into the lower atmosphere. The soil level of delayed fallout should correlate reasonably well with total rainfall within any limited geographical area for which the seasonal pattern of rainfall is similar.

Southern Hemisphere fallout is substantially all delayed fallout. The limited data for South American soils and Antarctica snow cores indicate roughly uniform fallout over the Southern Hemisphere, with the distribution modified principally by the rainfall pattern.

Interpretation of Northern Hemisphere data is complicated by the contribution of fallout from the numerous small atomic weapons tests. Highest observed levels of fall out are reported for the Northern United States, with about 30 millicuries of strontium 90 per square mile in the fall of 1956. It is difficult to attribute more than a minor proportion of this amount to fallout from small weapons tests. The Northern United States may be receiving a substantially larger amount of delayed fallout than the average world deposition.

An important gap in the information on the worldwide distribution of strontium 90 is the fallout over the oceans which comprise some three-fourths of the earth area. It is not possible to anticipate whether the oceans are receiving more or less than their proportionate share of delayed fallout.

In conclusion, the large uncertainties in the atmospheric circulation and mixing history for delayed fallout, coupled with uncertain contribution of small weapons tests in the middle latitudes for the Northern Hemisphere, limit the reliability of any statement of the fraction and the distribution of delayed fallout which has already come down. Similarly, no reliable estimate of future ground levels can be made. At best the delayed fallout will be distributed roughly uniformly over the world, with the distribution modified by the rainfall pattern. It is also possible that the Northern Hemisphere is receiving a disproportionately large share, with the highest levels in the high rainfall areas of the middle latitudes.

III. COMMENTS ON PROCEDURE FOR SAMPLING DELAYED FALLOUT

Upper air sampling devices currently in use are satisfactory for synoptic evaluation of the distribution of stratospheric debris. However, in view of the unknown size distribution of the submicron particulates in the stratosphere and the inherent inefficiency of upper air sampling devices, the current techniques are inadequate to assess the total concentration at any point in space and thus will not allow reliable assessment of the total stratospheric burden. New upper air sampling systems currently under development should overcome these limitations.

Ground collection and analysis techniques for the indirect assessment of delayed fallout are complicated by the experimental difficulties in the determination of fallout over the large ocean areas and in the identification of delayed fallout in the presence of fallout from summary weapons tests.

Project Sunshine Bulletin, No. 12[1]: Strontium 90 Concentration Data for Biological Materials, Soils, Waters and Air Filters

E. A. Martell, August 1, 1956 (revised January 1957)—The Enrico Fermi Institute for Nuclear Studies, the University of Chicago, Chicago, Ill.

INTRODUCTION

In this revised edition of Chicago Sunshine Bulletin No. 12 are presented all Sr–90 concentration data obtained by the University of Chicago Project Sunshine

[1] This work was supported by the Division of Biology and Medicine, U. S. Atomic Energy Commission, under contract AT (11–1)–281.

group for the period December 1, 1955, to termination of the work in August 1956. For cumulative results to December 1, 1955, see Chicago Sunshine Bulletin No. 11.[2] Results for samples assayed by the Nuclear Science and Engineering Corp., Pittsburgh, Pa., under subcontract, are included and are designated by the letter "P" following the Chicago Laboratory number (i. e., CL xxx–P).

This revised report includes all results and discussion contained in the original version of Chicago Sunshine Bulletin No. 12, August 1, 1956, plus additional results submitted to the Division of Biology and Medicine, United States Atomic Energy Commission, in a letter report, Chicago Sunshine Results, Final List, dated August 3, 1956. Data of the last two columns, table 6, pages 27 and 28, have been corrected to take into account the difference in ratio of available Sr–90 to available calcium in the electrodialyzed sample as compared with the original soil. The correction is substantial for calcareous soils. A new result is reported for the Brawley, California soil, CL 1127 (p. 44, this report), establishing a lower maximum level of Sr–90 for this arid area.

The data for all biological samples and soils are presented in units of one one-thousandth of the occupational tolerance dose of Sr–90 for an average man of 1,000 grams total body content of calcium. Thus the "sunshine unit" equals one one-thousandth microcuries of Sr–90 per kilogram of calcium or 2.2 disintegrations per minute of Sr–90 per gram of calcium.

Water and air concentration data are reported in disintegrations per minute of Sr–90 per unit volume.

A description of the chemical procedures and the absolute counting method employed by the Chicago Sunshine project group has been reported.[3]

A considerable portion of the data presented in this report has been discussed by W. F. Libby.[4 5] Some of the data of Bulletins 11 and 12 are summarized in graphical or tabular form and are briefly discussed in the following section of this report.

DISCUSSION OF RESULTS

I. Sr–90 surface air concentration data

Large air blower samples, collected over the last several years at the Naval Research Laboratory, Washington, D. C., by I. H. Blifford and associates, were made available to us for Sr–90 assay. Collections were made on Army Chemical Corps type V filters of 200 square inches area and of heavy asbestos fiber composition. Collection volumes ranged from about 1 to 5 million cubic feet of air for collection periods of 1 day to 1 week. The large blower samples which were analyzed from Sr–90 were collected from four locations: Washington, D. C.; Kodiak, Alaska; Port Lyautey, French Morocco; and Yokosuka, Japan. A summary of the Sr–90 concentration data, together with the location, collection period, and sample volume for each sample, is presented in the last section of this report.

The Washington, D. C., Sr–90 air-concentration data are presented in figure 1. For these samples, the volumes were computed from recorded flow rate data. Figure 2 shows the variation in total flow with length of the collection due to dust loading of filters at the Washington, D. C., station. This curve was obtained from Mr. Blifford at the Naval Research Laboratory, who indicated quite large variations of individual collection volumes from the average values shown.

The data for the three foreign stations are presented in figure 3. For these, the collection volumes were not monitored and the volume of each sample was estimated by assuming the effect of dust loading observed at Washington, D. C. (fig. 2), applied equally well at these other locations. The necessity of making this assumption imposes a restriction on comparison of relative air concentrations for the four locations but does allow us to consider the change in air concentration with time at each location.

The data for all four locations show generally the same concentration levels at any given time and all show a gradual and substantial increase during 1954. The concentrations observed at Kodiak, Alaska, during and following the spring 1952 tests are strikingly low by comparison with the 1954 and 1955 concentration data. The average Sr-90 activity in 10^6 cubic feet of surface air appears to have increased from a pre-Ivy test level of about 4 dpm. to a pre-Castle level of some 40 dpm. and a post-Castle level of some 200 dpm.

Comparison of the Sr-90 air concentration data with the daily total fission product beta activity data obtained by the NRL group indicates "apparent" ages for the mixed fission products of from 1 month to several years with wide variations during any given month. No conclusions with respect to the Sr-90 production date may be drawn from such data for a number of reasons. The size distribution of the original bomb debris is dependent on the energy yield, orientation, and environment of the weapon and for each case the mean size of particulates carrying Sr-90 is expected to be smaller than that of mixed fission products. Furthermore, the particulates may be further fractionated by the action of rains, depending on the efficiency of scavenging by rains as a function of particle size. Another complication is that imposed by the size-collection efficiency of the device itself. Additional difficulties are imposed by the close spacing of tests during the last several years. Finally, there are large day-to-day variations in surface concentration of Sr-90 and other fission products, apparently due to scavenging of surface air by vegetation and to the time interval between rains.

In spite of the many complicating factors indicated above which limit the meaningfulness of any individual measurement of Sr-90 concentration and its relation to total fission product activity or to other individual fission product concentration, the general features of the Sr-90 surface air concentration data shed considerable light on atmospheric circulation and storage of long lived fission products. The Sr-90 air concentration history shows a marked general increase following the Ivy and Castle tests and thus appears to directly relate to the increased stratospheric storage following these tests. The general equiv-

alence of the concentrations observed for the four stations, widely separated in geographical location, is strong indication that relatively old debris rather than fresh fission product activity is involved. Except for a few of the highest concentration values observed, the Sr–90 data do not reflect any considerable contribution from individual small-weapons tests for which tropospheric washout rates of several weeks or less have been estimated.

An air filter device, horizontally oriented near the ground surface in general, will not collect large particles which fall directly or particles trapped in raindrops. Instead, it will collect a portion of those particles which mix downward between rains and persist in surface air plus some of the particles carried in the air downdraft associated with rains for which the scavenging efficiency of rains is low. Thus, the Sr–90 surface air concentration data do not necessarily relate to the total deposition rate in any direct manner.

The Sr–90 concentrations observed in surface air during the fall 1954 and spring 1955 are an order of magnitude lower than the limited United States and British measurements of upper troposphere concentration during the same period. The numbers are not necessarily inconsistent when consideration is given to dilution by cleaner surface air during downward mixing, to reduction resulting from scavenging by rains, and to removal from surface air by the filtration action of vegetation foliage and the action of fog and dew. The mean troposphere concentration of Sr–90 is undoubtedly a factor of 5 to 10 times higher than surface air values and thus corresponds to a total tropospheric air burden of 1 megaton of fission or so. These considerations provide additional basis for the argument that the Sr–90 surface air concentration data relate to stratospheric debris since the total fission yield represented by this source will generally mask the Sr–90 produced in tests of small atomic weapons. The low concentrations observed at Kodiak during June and July 1952 provide the most convincing argument that Nevada tests, and thus small weapons tests generally, contribute negligibly to the Sr–90 concentration observed on surface air filters.

Thus, it appears that the measurement of Sr–90 on surface air filters provides a direct measure of the stratospheric burden and that the apparent seasonal variation in the Sr–90 surface air concentration may relate to seasonal variation in mixing through the tropopause and/or tropospheric washout rate.

II. Sr–90 in Chicago rains

A. *Summary of Chicago rain data, 1953 through 1955.*—Table 1 shows the estimated monthly and yearly totals of Sr–90 deposited per square foot in the Chicago area, together with totals for rains actually measured.

The 1953 rain samples were roof runoff samples collected by the Chicago Tritium research group. For these, it is assumed that the result in disintegrations per minute was constant for each rain, and the Sr–90 deposited per square foot was computed from the total precipitation in inches reported by the Weather Bureau for the University of Chicago station.

The 1954 samples were individual rains collected in a galvanized washtub on the roof of the Jones chemistry laboratory building. For these, the total sample activity divided by the collection area was taken as the Sr–90 deposited per square foot for individual rains.

For both 1953 and 1954 rains, the total monthly deposit was estimated by multiplying the deposit in disintegrations per minute per square foot per inch of rain for the rains measured by the total monthly precipitation in inches.

Table 2 shows the total monthly deposits for 1955 rains. At all three locations the 1955 collections were made in galvanized tubs, and the total monthly precipitation was taken. For these, the deposit per square foot was computed from total sample activity divided by collection area. The 1955 collections were made with the tubs exposed continuously, and thus any dry material falling out between rains was included in the sample.

TABLE 1.—*Sr^{90} deposited by 1953 and 1954 Chicago rains*

	1953 Chicago rains		1954 Chicago rains

December	5.5 (0.47 inch)	7.9	

[1] Based on assay of ¾ of total monthly rainfall.

B. *Test of rain-collection method.*—If the collection of precipitation is to be used as a method of following the deposition of fallout Sr-90, it would be highly desirable to increase the collection period to about 1 month. During a long period of collection, the collector would be alternately dry and wet. Under these circumstances, it may be considered that a significant amount of fallout would be blown out of the collector during dry periods between rains or accumulated in excess when the collector contained water.

As a test of these possibilities, a number of collections made at Chicago during March, April, and May 1955 included, in addition to the standard open tub, a second tub covered with a plastic sheet with a small center hole, and a third tub with the water level maintained at an inch or more by periodically adding water.

Results for the "covered" tub and "wet" tub collections have been reported in Chicago Bulletin No. 11 and in this report. In the case of the "wet" tub, the volume reported is that obtained from the collector area and depth of precipitation reported by the Weather Bureau for the University of Chicago station.

The total Sr-90 activity collected by each of these methods can be directly compared since the collection areas are equal. The data are as follows:

1. Period 1000, Mar. 16, 1955, to 0915, Mar. 21, 1955:

CL 459–P	Open tub	29.0±2.0 dpm total.
CL 460–P	Covered tub	31.8±2.2 dpm total.

2. Period 1530, Mar. 21, 1955, to 1000, Apr. 4, 1955:

CL 462 and 466	Open tub	45.1±4.0 dpm total.
CL 477	"Wet" tub	35.2±2.2 dpm total.

3. Period 0950, Apr. 4, 1955 to 1400, Apr. 14, 1955:

CL 551–P	Open tub	29.0±1.9 dpm total.
CL 552–P	Covered tub	34.3±2.4 dpm total.

4. Period 2100, Apr. 14, 1955, to 1630, Apr. 20, 1955:

CL 562–P	Open tub	53.5±3.3 dpm total.
CL 563–P	Covered tub	34.4±1.8 dpm total.

5. Period 1800, Apr. 28, 1955, to 0930, May 13, 1955:

CL 617–P	Open tub	67±7 dpm total.
CL 618–P	Covered tub	83±9 dpm total.
CL 619–P	"Wet" tub	72.8±4.9 dpm total.

6. Period 1100, May 13, 1955, to 1130, May 23, 1955:

CL 627–P	Open tub	90±5 dpm total.
CL 628–P	Covered tub	70±5 dpm total.

7. Period 1700, May 23, 1955, to 1030, June 6, 1955:

CL 648	Open tub	210±8 dpm total.
CL 645	Covered tub	239±12 dpm total.
CL 646	"Wet" tub	221±8 dpm total.

The agreement in total Sr^{90} activity collected by each of the several methods is gratifying. The only significant discrepancy is the low value for CL 563–P which might be explained by the occurrence of a very heavy rainfall with a possible resultant loss of sample due to splashing off the plastic cover. Another possibility is the occurrence of dry fallout which could have been blown off the plastic cover by surface winds. It appears that the Sr^{90} is water soluble at the time of collection and is not absorbed on the walls of the vessels. It is further indicate that, once deposited in rains, the Sr^{90} fallout does not blow around significantly.

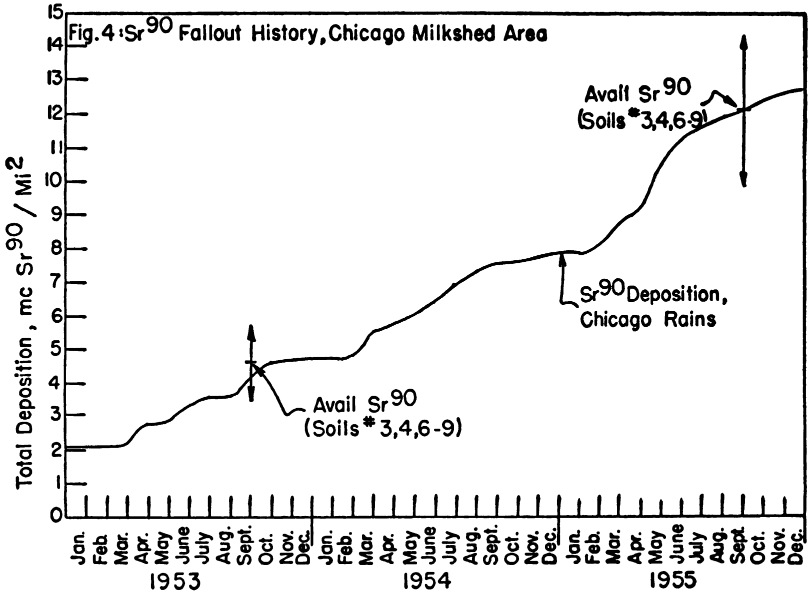
These results testify to the adequacy of the water-collection and chemical-separation procedures used and indicate that an open tub provides for reliable collection of precipitation for extended periods of time. Since the Sr activity is apparently quite soluble, large volume collections can be safely aliquotted to reduce the sample shipment problem. Thus, the collection of precipitation appears to be a practicable method to augment, or even replace, the sticky paper collector as a general method of worldwide monitoring.

C. *Solubility of Sr^{90} deposited in rains.*—The above indirect evidence for the solubility of the Sr^{90} activity in fallout is confirmed by the analysis and measurement of the insoluble residues from Chicago rains. The insoluble residues from two active Chicago rains, CL 320 and CL 407 and 408, initially separated by filtration, were fused with Na_2CO_3 and dissolved in HCl. Following a fuming nitric acid separation of strontium, the samples were reserved for yttrium 90 growth and milked for the Y^{90} activity. The results are shown in table 3 together with the Sr^{90} activity of the water soluble fraction.

TABLE 3.—*Solubility of Sr–90 in rains*

	CL 320	CL 407–8
1. Total Sr–90 activity in solution (dpm)	49.2±0.5	29.9±1.5
2. Total Sr–90 activity in insoluble residue (dpm)	≤0.6	0.7±0.1
3. Percent of total activity in insoluble residue	≤1.2	2.3±0.4

D. *Chicago fallout history from rain and soil data.*—The Sr^{90} data for Chicago rains and Chicago milkshed soils are summarized in figure 4 which gives the approximate total soil burden of Sr^{90} and its change with time over the 3-year period, January 1953 to December 1955. The curve is normalized to the average available Sr^{90} in 6 typical Chicago milkshed soils collected on September 29 and 30, 1955. The total monthly fallout in Chicago rains are taken from tables 1 and 2 above, and the method of measurement and data are discussed in the accompanying section. The Chicago milkshed soil data are discussed below.



The average available Sr^{90} observed for the same 6 soils samples in late September 1953 is also plotted. The agreement in this case may be partly fortuitous since the available Sr^{90} in the soils, that fraction extractable into normal neutral ammonium acetate, is somewhat less than the total.

From figure 3 it is clear that most of the fallout has been deposited since the beginning of 1953. The change in average annual slope indicates at least qualitatively the increasing annual contribution of stratospheric debris to total fallout. The general agreement between the change in soil level and cumulative fallout in rains during the intervening period is graphic indication that the scavenging of the atmosphere by rains is the primary mechanism of fallout. Sampling of rains with tubs continuously exposed will include collection of dry fallout of large particles which may be appreciable for considerable distances downwind of test areas during the first few days following an atomic test.

III. Results for 1955 Chicago milkshed samples

A. *1955 Chicago milkshed soils.*—Table 4 summarizes the results obtained for the Chicago milkshed soils collected September 29 and 30, 1955. The available calcium in grams per square foot was computed from Beltsville analyses of available calcium per unit weight of sample and total weight and area of sample collected. Strontium 90 analyses were made by the Chicago Sunshine Laboratory.

The samples were taken from the same fields of farms sampled in 1953 and again in 1954. Farms Nos. 3, 6, and 7 had been plowed recently. For each of these, 15 plugs, 3.5 inches in diameter, were taken to a depth slightly greater than apparent plow depth. On farm No. 7, two sets of samples were taken alternately spaced holes to provide a check on the reliability of sampling recently plowed fields. The agreement in the results of the duplicate samples is very striking.

The results in dpm per square foot apply to the available strontium 90 (i. e., extractable in normal neutral ammonium acetate) and not necessarily the total strontium 90 deposited per square foot. Although the Chicago rain data indicate that the strontium 90 is deposited in soluble form, it is recalled that 1953 soil samples fused with Na_2CO_3 following successive NH_4AC and HCl extraction showed appreciable residual strontium 90.

The average for the first 6 farms listed in table 4 is 970±180 dpm available strontium 90 per square foot, corresponding to about 12 millicuries per square mile for this area. The September 30, 1953, average for these same 6 soils was approximately 5 millicuries per square mile. The increase of 7 millicuries per square mile for the 2-year period is in surprisingly good agreement with the

total deposition of strontium 90 in Chicago rains over the same time interval (see fig. 4).

TABLE 4.—*Available Sr–90 in 1955 Chicago milkshed soils*

[1] Field recently plowed.

The soils for farms Nos. 11 and 12 are not typical for the Chicago milkshed area but are coarse sandy soils included in the selection because of their very low calcium level. These two soils show the lowest 1955 level and the lowest 2-year increase in available strontium 90. While it is possible that they received less fallout, it is more likely that something in the chemistry of these two soils acts to reduce the friction of "available" strontium 90. That these soils may be anomalous is further indicated by the unexpectedly low concentration of strontium 90 in the alfalfa grown on them (see table 5 and discussion on p. 22 below).

The strontium 90 measurements for the twelve Chicago milkshed soils collected in late September 1953 have been summarized and discussed elsewhere.[3] The 1953 soils show an average of about 50 percent of the total available strontium 90 in the top 1-inch layer for unplowed soils. The 1955 soils show about 80 percent of the total available strontium 90 in the top 2 inches of unplowed soils. Since this observation applies equally well to the soils showing the lowest total available strontium 90 (farms Nos. 11 and 12), it appears that the leaching of strontium 90 to greater depths by natural processes is very slow.

B. *1955 Chicago milkshed alfalfas.*—Results for the alfalfa samples are presented in table 5 together with the results for the soils from which they were collected. The soils are listed in order of decreasing concentration of available calcium in the 0 to 2 inch depth surface layer, as shown in column 2.

The soil levels of available strontium 90 in sunshine units are listed in the third column together with the depth of the soil sample assayed. The results for soil samples of 0 to 2-inch depth increase fairly regularly with decreasing calcium concentration. For the three recently plowed soils, the sunshine unit values of 0 to 2 inch depth are undoubtedly some 2 to 3 times the values given.

In controlled experiments, Menzel[4] has shown that the available strontium 90 to available calcium ratio in plants is about half the corresponding soil ratio. Under controlled field conditions, the relation of plant and soil level will be influenced by many complicating factors including possible leaf retention of strontium 90 fallout, variable root depth and soil moisture depth, the sharp gradient of strontium 90 concentration in the soil surface layer, and the application of fertilizers containing calcium. These factors undoubtedly account for considerable scatter in the results.

In the last column of table 5, the strontium 90 to calcium level in alfalfas are arbitrarily compared to the same ratio in the 0 to 2 inch layer of the soils on which they were grown. The results appear quite reasonable with the exception of those for McKee, Van Winkle, and Carver farms.

[4] Menzel, G. R., Soil Science 77, 419 (1954).

The high concentration for the McKee farm plant material may be explained by the fact that the sample taken was a mixture of bromegrass and ladino clover with shallower root depth than that of alfalfas and thus may relate to a higher soil level. Furthermore, the growth was short and sparse and was gleaned from several scattered patches apart from the point of soil sampling. Thus, differences in soil calcium or strontium 90 or a higher leaf retention effect may be involved. That this sample is not characteristic of the average McKee farm vegetation is indicated by the result of 0.51±0.03 S. U. for the bone of a McKee farm steer killed in September 1955 (see CW 813–P and compare with CL 1011 and 1012). The three 1955 Chicago milkshed animal bone samples show the lowest strontium 90 level for the farm with the highest soil calcium level and the highest bone level for that of the lowest calcium, as would normally be expected.

Dr. L. T. Alexander, Chief of the Department of Agriculture Soil Survey Laboratory, Beltsville, Md., has suggested that the low results for alfalfas grown on the two Plainfield sand soils (farms Nos. 11 and 12) may be due to the greater root depth which would result in their getting most of their calcium well below the surface and hence out of reach of the majority of the strontium 90 activity.

TABLE 5.—*Comparison of Sr–90 level in related alfalfa and soil samples*

Farm	Available Ca 0 to 2-inch depth (g/ft.²)	Sr–90 soil level, in sunshine units	Sr–90 plant level, in sunshine units	Ratio [1]
McKee (No. 9), McHenry County, Ill.	31.20	(0 to 2-inch), 9.8±0.4	30.5±1.70	3.10

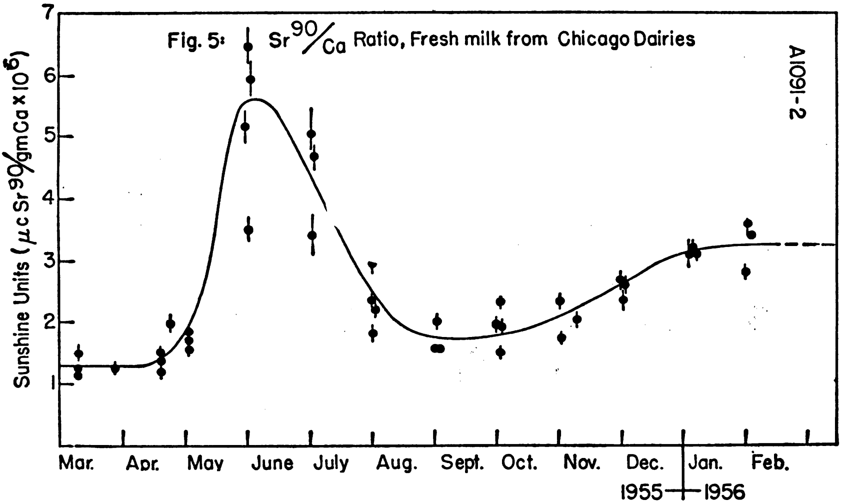
[1] Ratio=sunshine units plant/sunshine units soil over 0 to 2-inch depth. (For the 3 unplowed soils, the 0 to 2-inch depth concentration of Sr–90 is arbitrarily taken as 2.5 times that determined for the greater depth.

[2] Field recently plowed.

IV. Fresh milk from Chicago dairies

Samples of 2 to 3 gallons of fresh milk were obtained monthly from several of the larger Chicago dairies for 1 year beginning in March 1955. The results in sunshine units are presented in figure 5 which shows the very interesting seasonal variation in the Sr–90 level of forage and dairy products.



The January-February 1956 Sr–90 level appears to be a good average of the levels observed over the 1955 growing season. That is to be expected, since over the winter months the cows feed on hay gathered at various times during the previous growing season. Similarly, the March-April 1955 level must represent the average for 1954.

The sharp rise in the spring of 1955 may be due in part to leaf retention of fallout from the concurrent Nevada tests. However, the rise may be explainable in terms of other factors. When first pastured in the spring, the cows change from feed grown an average 8 months earlier to new growth, representing an increase in Sr–90 level due to the total additional Sr–90 fallout during the 8 months' period. Furthermore, the spring pasturage for the most part may be unplowed fields.

The fall-off during the summer may be due to several factors: A large proportion of feed from recently plowed fields, greater root depth and thus lower Sr–90 level for more mature plants, and lower Sr–90 retention in milk as a result of richer calcium diet. To the extent that leaf retention is involved, it should have lower effect in summer consistent with the lower observed fallout during the summer months (see 1955 Chicago rain data, table 2 above).

The increase from the March 1955 level to the February 1956 level is somewhat greater than the corresponding increase in the total Sr–90 soil level from July 1954 to July 1955 (see fig. 4). The greater increase in milk level may be the consequence of higher fallout, and thus higher leaf retention, in 1955 than in 1954. Another possible explanation would be the reduced effect of plowing on lowering the average Sr–90 level at root depth in successive years.

The data in figure 5 indicate that the sampling was surprisingly good, since the only considerable scatter occurs during the sharp spring rise. The monitoring of milk from large dairies appears to provide a good record of plant and dairy product activity levels over the growing season for a given area and also provides a basis for comparison of the activity of plants and dairy products from widely scattered areas.

V. Sr–90 content of foreign soils

The results of Sr–90 analyses for all foreign soil samples assayed since the publication of Chicago Sunshine Bulletin No. 11, December 1, 1955, are summarized in table 6. Results for earlier foreign soil measurements, which include most of the data for soils collected during and prior to the spring of 1954, have been reported by W. F. Libby.[4]

The results reflect the substantial increase in the worldwide distribution of Sr–90 fallout following the Castle tests. The increase is particularly striking for the Southern Hemisphere samples which show about an order of magnitude increase in the Sr–90 soil content for the period from spring 1954 to January 1956.

Two of the South American samples (Beltsville No. 56456 from Lima, Peru, and No. 56447 from Antofagasta, Chile) are representative of areas of very low rainfall. Comparing their results with those for the São Paulo, Brazil, and Antofagasta, Chile, soils indicates a striking dependence of the fallout on rainfall. The result for the Brawley, Calif., soil (CL 1127, reported on p. 44 ,this report), which shows ≤0.4 sunshine units, corresponding to ≤0.6 millicuries of Sr–90 per square mile, is equally convincing in this respect. It would appear that, except within several thousand miles downwind of test areas where large particles of dry debris may fall out directly for a short period following a test shot, precipitation must be the only important mechanism of fallout. This dependence can be further tested by relating the Sr–90 soil level to rainfall information for areas remote from test sites. The latitude dependence of fallout, pointed out by W. F. Libby,[4] should be taken into account when such a correlation is attempted.

I. Human bone—Continued	
D. Dentine:	
1. CL 665–P: Permanent teeth from persons over 15 years of age, Bristol, England, furnished by Dr. Shields Warren, Cancer Research Institute, New England Deaconess Hospital, Boston, Massachusetts, No. L3, collected January to April 1955, 32.32 g ash, 12.5 g Ca	.026±.011
II. Animal bone:	
A. United States:	
1. Chicago Milkshed Farms: Collected by Dr. E. A. Martell:	
a. CL 813–P: Leg bone of Holstein-Angus, age 1½ years, McKee Farm (No. 9), McHenry County, Illinois, killed September 22, 1955, 1374 g ash, 35.3 g Ca	.51±.03
b. CL 1012–P: Steer leg bones, age 19 months, Swanson Farm (No. 3), Winnebago County, Illinois, killed middle of November 1955, 279.8 g ash, 19.5 g Ca	2.09±.11
c. CL 1011–P; Steer leg bone, age 15 months, Grabow Farm (No. 1), Rock County, Wisconsin, killed January 15, 1956, 440.2 g ash, 122.6 g Ca	5.50±.27
2. Interlaboratory check sample, Cornell lamb bone, New York, age 6 months, furnished by Dr. Lyle T. Alexander, Beltsville No. 551512, killed September 15, 1955. Four replicates assayed as individual samples:	
a. CL 841: Cornell lamb bone No. 31, 24.86 g ash, 8.96 g Ca	4.45±.34
b. CL 842: Cornell lamb bone No. 32, 25.07 g ash, 9.26 g Ca	5.14±.23
c. CL 843–P: Cornell lamb bone No. 33, 24.86 g ash, 8.26 g Ca	6.98±.34
d. CL 844–P: Cornell lamb bone No. 34, 24.95 g ash, 11.1 g Ca	4.45±.24
3. Interlaboratory check sample, calf bone, age 9 months, Tifton, Georgia, Beltsville No. 551168, killed last week in October 1955:	
a. CL 972: 31.8 g ash, 12.05 g Ca	12.9± .6
b. CL 973: 30.87 g ash, 11.42 g Ca	10.3± .3
c. CL 974–P: 32.93 g ash, 12.2 g Ca	12.7± .7
d. CL 975–P: 31.45 g ash, 11.9 g Ca	11.4± .6
B. Foreign, Southern Hemisphere:	
1. CL 1130–P: Lamb bones, Montaro Valley, Huan Cayo, Peru, collected by Dr. M. Drosdoff, ICA, USOM to Peru, Beltsville No. 56475, received May 23, 1956, 144.2 g ash, 18.43 g Ca	7.48±.44
III. Animal products:	
A. Cheese:	
1. United States:	
a. CL 707–P: Domestic Swiss, Wisconsin, 15 lbs. purchased from V. Berg, Chicago, August 25, 1955, manufactured April 19, 1955, 281.2 g ash, 51.0 g Ca	10.4± .4
b. CL 836: Domestic Münster, Dodge County, Wisconsin, 19.5 lbs. purchased from V. Berg, Chicago, November 30, 1955, manufactured October 11, 1955, 271.5 g ash, 20.0 g Ca	6.7± .3
c. CL 838: Domestic Swiss, Green County, Wisconsin, 13.75 lbs. purchased from V. Berg, Chicago, November 30, 1955, manufactured September 2, 1955, 212.5 g ash, 56.4 g Ca	6.8± .2

B. Other United States:	
1. Interlaboratory check sample, Bermuda grass, Tifton, Georgia, Beltsville No. 551528, harvested in June 1955:	
a. CL 968–P: 124.4 g ash, 4.71 g Ca	42. 0±1. 9
b. CL 970: 124.4 g ash, 4.39 g Ca	40. 0±2. 0
2. Interlaboratory check sample, mixed hay, New York, furnished by Dr. L. Alexander, Beltsville No. 551513, grown during August and September 1955:	
a. CL 847–P: Cornell No. 3, 90.5 g ash, 12.0 g Ca	19. 7± .8
b. CL 848–P: Cornell No. 4, 89.7 g ash, 12.0 g Ca	17. 9± .9
3. Brawley, California: Furnished by Edward Noble, Southwestern Irrigation Field Station. Collection arrangements made by Dr. Lyle T. Alexander, Plant Industry Station, U. S. Department of Agriculture, Beltsville, Maryland, January 5, 1956:	
a. CL 1059–P: Lettuce, 57.3 g ash, 2.68 g Ca	.39±. 05
b. CL 1060–P: Broccoli, 74.4 g ash, 7.90 g Ca	.25±. 08
c. CP 1061–P: Peas, 56.1 g ash, 5.67 g Ca	1. 34±. 08
d. CL 1062–P: Alfalfa, 49.9 g ash, 5.43 g Ca	2. 13±. 22
V. Soil: All soil samples listed below were obtained by Dr. L. T. Alexander and extracted at the Soil Survey Laboratory, U. S. Department of Agriculture, Beltsville, Maryland. During the Spring of 1956, the Beltsville laboratory discontinued the ammonium acetate extraction procedure in favor of electrodialysis extraction. The method of extraction is indicated for each sample. Soil Survey Laboratory analyses on these samples include the determination of Na, K, Mg, Ca and Sr:	
A. Chicago Milkshed: Collected by Dr. L. Alexander, Soil Survey Laboratory, Plant Industry Station, U. S. Department of Agriculture, Beltsville, Maryland, and Dr. E. A. Martell, Enrico Fermi Institute for Nuclear Studies, University of Chicago, Chicago, Illinois, September 29 and 30, 1955:	
1. CL 1019: Swanson Farm (No. 3), Winnebago County, Illinois, Carrington-like silt loam, Beltsville No. 551503, NH_4AC extraction of 4 lbs, soil, 0–8″ depth, 20.0 g oxalate, 7.54 g oxide, 5.39 g Ca	6. 83±. 8

2. Holcomb Farm (No. 4), Rock County, Wisconsin, Carrington silt loam:	
a. CL 956: Beltsville No. 551500, NH_4AC extraction of 4 lbs. soil, 0–2″ depth, 12.1 g oxalate, 6.82 g oxide, 3.06 g Ca	26.7±1.0
b. CL 957: Beltsville No. 551501, NH_4AC extraction of 4 lbs. soil, 2–6″ depth, 12.1 g oxalate, 6.21 g oxide, 3.18 g Ca	3.81±.14
3. CL 1018: Premo Farm (No. 6), Columbia County, Wisconsin, Miami silt loam, Beltsville No. 551502, NH_4AC extraction of 4 lbs. soil, 0–6″ depth, 11.25 g oxalate, 3.94 g oxide, 2.79 g Ca	15.0± .5
4. Kurpeski Farm (No. 7), McHenry County, Illinois, Miami silt loam:	
a. CL 886: Beltsville No. 551496, Sample A, NH_4AC extraction of 4 lbs. soil, 0–6 or 7″ depth, 8.51 g oxalate, 3.21 g oxide, 2.24 g Ca	11.9± .5
b. CL 887: Beltsville No. 551497, Sample B, NH_4AC extraction of 4 lbs. soil, 0–6 or 7″ depth, 8.90 g oxalate, 3.35 g oxide, 2.36 g Ca	12.6± .5
5. Austin Farm (No. 8), McHenry County, Illinois, Miami silt loam:	
a. CL 1020: Beltsville No. 551504, NH_4AC extraction of 4 lbs. soil, 0–2″ depth, 5.71 g oxalate, 2.21 g oxide, 1.57 g Ca	49.9± 1.5
b. CL 1021: Beltsville No. 551505, NH_4AC extraction of 4 lbs. soil, 2–6″ depth, 4.08 g oxalate, 1.6 g oxide, 1.19 g Ca	9.6± .4
6. McKee Farm (No. 9) McHenry County, Illinois, Drummer silty clay loam:	
a. CL 888: Beltsville No. 551498, NH_4AC extraction of 4 lbs. soil, 0–2″ depth, 30.25 g oxalate, 11.31 g oxide, 7.04 g Ca	9.8± .4
b. CL 955: Beltsville No. 551499, NH_4AC extraction of 4 lbs. soil, 2–6″ depth, 30.6 g oxalate, 17.44 g oxide, 7.91 g Ca	.99± .04
7. Van Winkle Farm (No. 11), Will County, Illinois, Plainfield sand:	
a. CL 1022: Beltsville No. 551508, NH_4AC extraction of 4 lbs. soil, 0–2″ depth, 4.31 g oxalate, 1.66 g oxide, 1.19 g Ca	65.1± 2.6
b. CL 1023: Beltsville No. 551509, NH_4AC extraction of 4 lbs. soil, 2–6″ depth, 2.44 g oxalate, 0.94 g oxide, 0.67 g Ca	10.0± 0.4
8. Carver Farm (No. 12), Will County, Illinois, Plainfield sand:	
a. CL 1024: Beltsville No. 551510, NH_4AC extraction of 4 lbs. soil, 0–2″ depth, 4.43 g oxalate, 1.70 g oxide, 1.22 g Ca	64.5± 1.3
b. CL 1025: Beltsville No. 551511, NH_4AC extraction of 4 lbs. soil, 2–6″ depth, 2.98 g oxalate. 1.15 g oxide, 0.97 g Ca	14.0± 0.7
B. Other United States soils:	
1. Interlaboratory check sample, Ithaca, New York, September 15, 1955, electrodialysis extraction of 4 lbs. soil, 0–2″ depth:	
a. CL 1039: Beltsville No. 551186A, 18.28 g oxalate, 6.93 g oxide, 4.96 g Ca	21.5± 1.3
b. CL 1040–P: Beltsville No. 551186B, 18.22 g oxalate, 6.84 g oxide, 4.89 g Ca	17.8± 1.0

2. Interlaboratory check sample, Tifton, Georgia, November 2, 1955, electrodialysis extraction of 4 lbs. soil, 0–4'' depth:	
a. CL 1041–P: Beltsville No. 551523A, 0.698 g oxalate, 0.26 g oxide, 0.186 g Ca	164.0±12.0
b. CL 1042: Beltsville No. 551523B, 0.59 g oxalate, 0.22 g oxide, 0.16 g Ca	178.2± 7.1
3. CL 1127: Brawley, California, Beltsville No. 56316, collected January 5, 1956, electrodialysis extraction of 4 lbs. soil, 0–6'' depth, 16.56 g oxalate, 6.35 g oxide, 4.54 g Ca	(≤.8),[1]≤.4
C. Foreign, Northern Hemisphere:	
1. CL 1065: England, Beltsville No. 54675B, obtained by Dr. L. Alexander in July 1954, extracted by fusion of a 100 gram subsample of a 4 lb. electrodialyzed soil sample, 0–3'' depth, 4.15 g oxalate, 1.59 g oxide, 0.136 g. Ca. (1.2±0.3 dpm Sr–90 total sample activity)	4.0±1.0
2. CL 1095–P: Calcareous, Paris, France, Beltsville No. 55614, obtained by Dr. L. Alexander, February 16, 1955, electrodialysis extraction of 4 lbs. soil, 0–4'' depth, 29.30 g oxalate, 11.06 g oxide, 7.90 g Ca	.69± .05
3. CL 881: Italy, Beltsville No. 55772, obtained by Dr. L. Alexander, February 5, 1955, NH_4AC extraction of 4 lbs. soil, 0–4'' depth, 43.1 g oxalate, 16.54 g oxide, 11.5 g Ca	1.64± .05
4. CL 882: Turkey, Beltsville No. 55877, obtained by Dr. L. Alexander, February 7, 1955, NH_4AC extraction of 4 lbs. soil, 0–4'' depth, 44.6 g oxalate, 16.96 g oxide, 12.0 g Ca	1.28± .07
5. CL 883: Turkey, Beltsville No. 551284, obtained by Dr. L. Alexander, February 28, 1954, NH_4AC extraction of 4 lbs. soil, 0–2'' depth, 42.8 g oxalate, 16.31 g oxide, 11.5 g Ca	2.44± .13
6. CL 884: Turkey, Beltsville No. 551285, obtained by Dr. L. Alexander, February 28, 1954, NH_4AC extraction of 4 lbs. soil, 0–2'' depth, 47.5 g oxalate, 18.28 g oxide, 12.8 g Ca	1.52± .05
7. CL 885: Turkey, Beltsville No. 551286, obtained by Dr. L. Alexander, February 28, 1954, NH_4AC extraction of 4 lbs. soil, 0–2'' depth, 53.9 g oxalate, 20.67 g oxide, 13.6 g. Ca	1.29±0.06
8. CL 1046–P: Calcareous, Kohler Yard, Turkey, Beltsville No. 55878A, obtained by Dr. L. Alexander, February 7, 1955, electrodialysis extraction (48-hour period) of 4 lbs. soil, 0–4'' depth, 17.11 g oxalate, 5.50 g oxide 4.72 g Ca	2.4±0.2
9. CL 1047–P: Calcareous, Kohler Yard Turkey, Beltsville No. 55878B, obtained by Dr. L. Alexander, February 7, 1955, electrodialysis extraction (additional 24-hour period) of 4 lbs. soil, 0–4'' depth, 10.64 g oxalate, 4.03 g oxide, 2.88 g Ca	1.01±0.12
10. CL 1094–P: Calcareous, Damascus Syria, Beltsville No. 55590, obtained by Dr. L. Alexander, February 11, 1955, electrodialysis extraction of 4 lbs. soil, 0–4'' depth, 20.30 g oxalate, 7.70 g oxide, 5.50 g Ca	1.40±0.10

[1] New result obtained following strontium separation and barium chromate scavenging to remove radium activity.

30. CL 771–P: Rain, 1.07 gal., 0.55″ equivalent, collected 1110, October 7, 1955, to 1027, October 12, 1955	9.02±0.52
31. CL 772–P: Rain, 1.16 gal., 0.59″ equivalent, collected 1027, October 12, 1955, to 1021, October 17, 1955	8.4±0.5
32. CL 799–P: Rain, 0.79 gal., 0.40″ equivalent, collected 1021, October 17, 1955, to 0811, October 24, 1955	26.5±1.5
33. CL 825–P: Rain, 1.04 gal., 0.53″ equivalent, collected 0811, October 24, 1955, to 1010, October 31, 1955	10.1±0.5
34. CL 828–P & 830–P: Rain, 1.84 gal., 0.94″ equivalent, collected 1010, October 31, 1955, to 1030, November 17, 1955	21.0±1.0
35. CL 831–P: Snow, 0.535 gal., 0.27″ equivalent, collected 1030, November 17, 1955, to 0949, November 21, 1955	22.3±1.0

[2] See discussion, Test of Rain Collection Method (p. 622).

Chicago sunshine results for period Dec. 1, 1955, to Aug. 1, 1956—Continued

Sample	*Sunshine units*
VI. Precipitation—Continued	
A. Chicago, Illinois—Continued	
36. CL 837–P: Rain, 0.147 gal., 0.075″ equivalent, collected 0949, November 21, 1955, to 0920, November 23, 1955	36. 0±4. 7
37. CL 840–P: Snow, 0.122 gal., 0.062″ equivalent, collected 0920, November 23, 1955, to 1055, November 28, 1955	11. 7±2. 7
38. CL 871–P: Snow, 0.116 gal., 0.059″ equivalent, collected 1055, November 28, 1955, to 1100, December 2, 1955	28. 6±3. 4
39. CL 872–P: Snow, 0.31 gal., 0.16″ equivalent, collected 1100, December 2, 1955, to 1120, December 5, 1955	19. 0±1. 4
40. CL 954–P: Snow, 0.15 gal., 0.077″ equivalent, collected 1120, December 5, 1955, to 0800, December 21, 1955	53. 0±7. 0
41. CL 976–P: Snow, 0.082 gal., 0.042″ equivalent, collected 0800, December 21, 1955, to 1115, January 16, 1956	440. 0±25. 0
B. Insoluble residue from Chicago rains:	
1. Insoluble residue from rain, CL 320: 1.82 gal., 0.930″ equivalent, collected December 24, 1954, to December 27, 1954. The filtered insoluble residue was fused with sodium carbonate before assay:	
Total Sr–90 activity insoluble residue: ≤0.6 dpm.	
Total Sr–90 activity in solution: 49.2±0.5 dpm.	
2. Insoluble residue from rain, CL 407 and 408: 0.71 gal., 0.36″ equivalent, collected February 18, 1955, to 0900, February 21, 1955. The filtered insoluble residue was fused with sodium carbonate before assay:	
Total Sr–90 activity insoluble residue: 0.7±0.1 dpm.	
Total Sr–90 activity in solution: 29.9±1.5 dpm.	
C. Washington, D. C.: Collected at the Naval Research Laboratory. Samples were taken by direct fall into galvanized tubs on the roof of one of the NRL buildings. The precipitation in inches is that reported by the local Weather Bureau station for the period of sample collection:	
1. CL 790: Rain, 2.40 gal., 0.61″, collected 2000, April 11, 1955, to 0400, April 12, 1955	34. 3±1. 4
2. CL 791–P: Rain, 2.92 gal., 0.68″, collected 0030 to 1500, April 14, 1955	25. 6±3. 5
3. CL 792: Rain, 0.845 gal., 0.21″, collected 2315 to 2400, April 14, 1955	39. 0±1. 7
4. CL 793–P: Rain, 1.60 gal., 0.23″, collected 2100, April 21, 1955, to 0245, April 22, 1955	46. 7±2. 2
5. CL 794: Rain, 0.697 gal., 0.21″, collected 0415, April 24, 1955, to 0300, April 25, 1955	195. 0±4. 3
6. CL 795–P: Rain, 2.30 gal., 0.39″, collected 1500, April 25, 1955, to 0700, April 26, 1955	15. 5±0. 6
7. CL 797: Rain, 0.771 gal., 0.19″, collected 1630 to 2030, May 20, 1955	112. 9±2. 0
8. CL 798–P: Rain, 1.17 gal., 0.29″, collected 1245 to 1400, May 22, 1955	1. 92±0. 22
D. Pittsburgh, Pennsylvania: Collected by the Nuclear Science and Engineering Corporation. Samples were taken by direct fall into galvanized tubs on the roof of the laboratory building. The precipitation in inches is that reported by the local Weather Bureau station for the period of sample collection:	
1. CL 876–P: Rain, PL–20–RW, 2.47 gal., 0.48″, collected 1200, July 10, 1955, to 1000, July 19, 1955	16. 6±1. 5

Chicago sunshine results for period Dec. 1, 1955, to Aug. 1, 1956—Continued

E. Pittsburgh, Pennsylvania—Continued	
2. CL 877–P: Rain, PL–21–RW, 5.70 gal., 0.65″, collected 1000, July 19, 1955, to 1100, July 25, 1955	18.8±1.4
3. CL 878–P: Rain, PL–22–RW, 4.40 gal., 0.60″, collected 1100, July 25, 1955, to 0900, July 28, 1955	8.2±0.5
4. CL 879–P: Rain, PL–23–RW, 1.98 gal., 0.18″, collected 0900, July 28, 1955, to 1000, August 6, 1955	8.7±1.0
5. CL 961–P: Rain, PL–24–RW, 0.86 gal., 0.18″, collected 1000, August 6, 1955, to 1500, August 8, 1955	10.8±1.0
6. CL 962–P: Rain, PL–25–RW, 4.91 gal., 1.98″, collected 1500, August 8, 1955, to 1630, August 11, 1955	5.55±0.32
7. CL 982–P: Rain, PL–26–RW, 7.6 gal., 2.24″, collected 1630, August 11, 1955, to 1030, August 16, 1955	31.0 ±3.0
8. CL 983–P: Rain, PL–27–RW, 4.0 gal., 1.71″, collected 1030, August 16, 1955, to 1700, August 23, 1955	83.0±5.0
9. CL 963–P: Rain, PL–28–RW, 0.395 gal., 0.66″, collected 1700, August 23, 1955, to 1600, August 31, 1955	31.6±2.6
10. CL 964–P: Rain, PL–29–RW, 4.4 gal., 1.84″, collected 1600, August 31, 1955, to September 28, 1955	9.75±0.59
11. CL 965–P: Rain, PL–30–RW, 2.0 gal., 0.76″, collected September 28, 1955, to October 10, 1955	10.7±0.6
12. CL 966–P: Rain, PL–31–RW, 3.9 gal., 1.32″, collected October 10, 1955, to October 18, 1955	14.2±0.6
13. CL 984–P: Rain, PL–32–RW, 0.465 gal., 0.09″, collected October 18, 1955, to October 20, 1955	34.0±1.6
14. CL 985–P: Rain, PL–33–RW, 1.14 gal., 0.42″, collected October 20, 1955, to 1615, October 24, 1955	16.1±0.8
15. CL 986–P: Rain, PL–34–RW, 0.508 gal., 0.28″, collected 1615, October 24, 1955, to 1700, October 29, 1955	50.5±2.5
16. CL 987–P: Rain, PL–35–RW, 0.715 gal., 0.40″, collected 1700, October 29, 1955, to 0845, October 31, 1955	38.4±1.9
17. CL 988–P: Rain, PL–36–RW, 0.465 gal., 0.31″, collected 0845, October 31, 1955, to 1630, November 12, 1955	60.0±2.9
18. CL 989–P: Rain, PL–37–RW, 0.402 gal., 0.08″, collected 1630, November 12, 1955, to 1630, November 14, 1955	22.6±1.4
19. CL 990–P: Rain, PL–38–RW, 6.18 gal., 2.25″, collected 1630, November 14, 1955, to 1100, November 21, 1955	4.43±0.19
20. CL 1032–P: Rain, PL–39–RW, 2.06 gal., 0.35″, collected 1100, November 21, 1955, to 1400, December 3, 1955	17.0 ±1.0
21. CL 991–P: Rain, PL–40–RW, 0.0238 gal., 0.07″, collected 1400, December 3, 1955, to 1400, December 14, 1955	319.0±24.0
22. CL 1033–P: Rain, PL–41–RW, 0.025 gal., 0.05″, collected 1400, December 14, 1955, to 1400, December 24, 1955	520.0±60.0
23. CL 1066–P: Rain, PL–42–RW, 4.34 gal., 2.63″, collected 1400, December 24, 1955, to 1600, February 3, 1956	29.0±3.0
24. CL 1088–P: Rain, PL–43–RW, 6.05 gal., 2.10″, collected 1600, February 3, 1956, to 1000, February 13, 1956	16.9±1.3
25. CL 1089–P: Rain, PL–44–RW, 4.10 gal., 2.95″, collected 1000, February 13, 1956, to 1400, February 27, 1956	32.2±1.9

B. Sr–90 Surface Air Concentration, Foreign Locations: There is considerable uncertainty in the air volumes of samples collected at Kodiak, Alaska, Port Lyautey, French Morocco, and Yokosuka, Japan, because the flow rate is not directly recorded. For the earliest reports of air filter data for these three locations, the rated flow rate times the total collection period was taken as the collected air volume. Because the flow rate falls off substantially as dust accumulates on the filter, those samples were overestimated in volume and thus the reported air concentration data were too low. It is considered that a better estimate of their air volume is provided by the average Washington, D. C. volumes for equivalent collection periods. On this basis, the relative air concentration data should be considerably improved, although their absolute value may be in error by as much as 50 percent or so. All the earlier reported air filter data for Kodiak, Port Lyautey, and Yokosuka have been estimated on this basis, and the new results are presented below.

1. KODIAK, ALASKA

CL No.	Collection period	Volume ($ft^3 \times 10^{-4}$)	DPM Sr-90/10^6 ft^3

948-P	Sept. 23-25, 1955	~3.0	~70

Chicago sunshine results, final list (originally submitted to the Divisions of Biology and Medicine, USAEC, in letter report of August 3, 1956)

Sample — *Sunshine units*

I. Human bone: In all cases, date given corresponds to date of death or post mortem:
  A. United States: Furnished by Dr. Shields Warren, Cancer Research Institute, New England Deaconess Hospital, Boston, Massachusetts:
    1. CL 873-P: Combination of 2 samples, age range 65-67 years, 149.9 g ash, 58.3 g Ca — 0.026 ± 0.005
      a. No. 160739, 67 yrs., April 20, 1955, Massachusetts, tibia and fibula.
      b. No. 161622, 65 yrs., May 25, 1955, Massachusetts, femur.
    2. CL 874-P: Combination of 3 samples, age range 71-78 years, 306.2 g ash, 121.8 g Ca — 0.020 ± 0.005
      a. No. 161203, 71 yrs., May 10, 1955, Massachusetts, femur and tibia shanks.
      b. No. 161205, 72 yrs., May 10, 1955, Massachusetts, femur and tibia shanks.
      c. No. 161526, 78 yrs., May 21, 1955, Massachusetts, femur and tibia shanks.
    3. CL 1159-P: Age 51 years, New York, No. 162471, July 5, 1955, left tibia, 66.5 g ash, 5.85 g Ca — 2.26 ± 0.16
    4. CL 1154-P: Age 13 years, W. Buxton, Maine, A-56-13, January 16, 1956, rib and vertebral fragments, 17.50 g ash, 6.64 g Ca — 0.14 ± 0.01
    5. CL 1146-P: Age 2 9/12 years, Lewiston, Maine, A-56-16, January 18, 1956, rib and vertebral fragments, 8.86 g ash, 3.32 g Ca — 0.54 ± 0.05
    6. CL 1155-P: Age 13 7/12 years, Norfolk, Massachusetts, A-56-20, January 26, 1956, rib and vertebral fragments, 19.35 g ash, 7.47 g Ca — 0.36 ± 0.03

Chicago sunshine results, final list (originally submitted to the Divisions of Biology and Medicine, USAEC, in letter report of August 3, 1956)—Con.

I. Human bone—Continued	
A. United States—Continued	
7. CL 1151–P: Combination of 2 samples, age range 7–10 years, 19.34 g ash, 6.62 g Ca	0.14±0.02
a. A–56–41, 7⁸⁄₁₂ yrs., Feb. 22, 1956, Concord, Massachusetts, rib and vertebral fragments.	
b. A–56–26, 9¹⁰⁄₁₂ yrs., Feb. 3, 1956, Brighton, Massachusetts, rib and vertebral fragments.	
8. CL 1147–P: Combination of 2 samples, age range 3–4 years, 14.34 g ash, 5.15 g Ca	0.32±0.03
a. A–56–25, 3⁸⁄₁₂ yrs., Feb. 3, 1956, Norwood, Massachusetts, vertebral fragments.	
b. A–56–46, 3¹⁰⁄₁₂ yrs., Feb. 23, 1956, Needham, Massachusetts, vertebral fragments.	
9. CL 1141–P: Combination of 2 samples, age range 3–6 days, 9.96 g ash, 3.78 g Ca	0.54±0.05
a. A–56–43, 3 days, Feb. 23, 1956, Boston, Massachusetts, rib and vertebral fragments.	
b. A–56–35, 6 days, Feb. 16, 1956, Lynn, Massachusetts, rib and vertebral fragments.	
10. CL 1150–P: Combination of 2 samples, age range 7–7½ years, 24.8 g ash, 8.23 g Ca	0.095±0.011
a. A–56–51, 7⁸⁄₁₂ yrs., Feb. 29, 1956, Canton, Massachusetts, rib and vertebral fragments.	
b. Barbara Mann, 7½ yrs., early 1956, Wallingford, Connecticut, rib and vertebral fragments.	
11. CL 1145–P: Combination of 3 samples, age range 1 to 2⁸⁄₁₂ years, 21.65 g ash, 9.29 g Ca	0.96±0.07
a. A–56–37, 1³⁄₁₂ yrs., Feb. 17, 1956, Warrick, Rhode Island, scalp, rib and vertebral fragments.	
b. A–56–64, 1⁵⁄₁₂ yrs., March 10, 1956, North Adams, Massachusetts, scalp, rib and vertebral fragments.	
c. A–56–31, 2⁸⁄₁₂ yrs., early 1956, Natick, Massachusetts, scalp, rib and vertebral fragments.	
12. CL 1148–P: Combination of 2 samples, age range 4 to 4⁷⁄₁₂ years, 18.08 g ash, 5.83 g Ca	0.17±0.01
a. A–56–40, 4 yrs., Feb. 19, 1956, Massachusetts, rib and vertebral fragments.	
b. A–56–75, 4⁷⁄₁₂ yrs., March 26, 1956, Hyannis, Massachusetts, rib and vertebral fragments.	
13. CL 1143–P: Combination of 2 samples, age range 5 weeks to 5 months, 12.11 g ash, 4.17 g Ca	1.13±0.12
a. A–56–71, 5 wks., March 20, 1956, Humarock, Massachusetts, scalp, rib and vertebral fragments.	
b. A–56–47, 5 mo., Feb. 25, 1956, Waltham, Massachusetts, scalp, rib and vertebral fragments.	
14. CL 1149–P: Combination of 3 samples, age range 4½–7 years, 29.1 g ash, 10.92 g Ca	0.21±0.03
a. A–56–49, 4⁵⁄₁₂ yrs., Feb. 20, 1956, Burlington, Vermont, rib and vertebral fragments.	
b. A–56–89, 5¹⁰⁄₁₂ yrs., Apr. 17, 1956, Fair Haven, Vermont, rib and vertebral fragments.	
c. A–56–27, 6¹¹⁄₁₂ yrs., Feb. 3, 1956, Barre, Vermont, rib and vetebral fragments.	
15. CL 1142–P: Combination of 2 samples, age range 7–9 days, 6.42 g ash, 2.28 g Ca	0.47±0.04
a. A–56–54, 7 days, March 3, 1956, Brockton, Massachusetts, rib and vertebral fragments.	
b. A–56–60, 9 days, March 7, 1956, Newton, Massachusetts, rib and vertebral fragments.	
16. CL 1158–P: Age 3⁸⁄₁₂ years, New Orleans, Louisiana, A–56–57, March 5, 1956, vertebral fragments, 4.21 g ash, 2.41 g Ca	0.29±0.04

VIII. Surface Air Concentration: Air filter samples provided by Mr. I. H. Blifford, Naval Research Laboratory, Washington, D. C.	
A. Air filters, Washington, D. C.:	
1. CL 915–P: Collected June 2–3, 1955, volume 1.65×10^6 ft³, total dpm 224±12	1350. ±7.0
2. CL 916–P: Collected June 8–10, 1955, volume 3.17×10^6 ft³, total dpm 66±5	21.0±2.0
3. CL 1052–P: Six small filters, collected February 23–28, 1955, 0.258×10^6 ft³ total air volume	244.0±29.0
B. Air filters, Kodiak, Alaska:	
1. CL 938–P: Collected August 16–23, 1954, $\sim 4.4\times 10^6$ ft³	~33
C. Air filters, Pearl Harbor, T. H.:	
1. CL 1053–P: Fifteen small filters, collected January 1–20, 1954, 0.645×10^6 ft³ total air volume	34.0±4.5
2. CL 1054–P: Ten small filters, collected January 21–31, 1954, 0.43×10^6 ft³ total air volume	51.9±6.0
3. CL 1055–P: Twelve small filters, collected February 1–14, 1954, 0.52×10^6 ft³ total air volume	41.6±4.8
4. CL 1056–P: Twelve small filters, collected February 15–28, 1954, 0.52×10^6 ft³ total air volume	25.4±3.8

Naval Research Laboratory

Information on Fallout

As prepared by Luther B. Lockhart, Jr. (see biography p. 324), Head, High Polymers Branch, Chemistry Division

(Enclosure: (1) Abstract of report entitled, "Atmospheric Radioactivity Along the 80th Meridian, 1956"; (2) NRL Memo Report 626 and monthly letter reports entitled, "Radioactivity of Air and Fallout Samples Collected at Sites on the 80th Meridian.")

1. The U. S. Naval Research Laboratory has had in effect since 1948 a long-range program on the radioactivity of the air. This program has included the study of methods of collecting and estimating both the natural and fission product activity of the air and also the routine measurement of the gross B-activity of the air since early 1950. Documents relating to atmospheric radioactivity and fallout include the following:

(*a*) NRL Report 4036 (September 1952), "On the Natural Radioactivity in the Air," I. H. Blifford, Jr., L. B. Lockhart, Jr., and H. B. Rosenstock.

(*b*) NRL Report 4069 (October 1952), "The Collection of Long-lived Natural Radioactive Products from the Atmosphere," P. King, L. B. Lockhart, Jr., et al.

(*c*) NRL Report 4607 (Nov. 4, 1955), "Relationship between the Air Concentration of Radioactive Fission Products and Fallout," I. H. Blifford, Jr., L. B. Lockhart, Jr., and R. A. Baus.

(*d*) NRL Report 4760 (June 4, 1956), "Radioactivity of the Air," I. H. Blifford, Jr., H. Friedman, L. B. Lockhart, Jr., and R. A. Baus.

(*e*) NRL Memo Report 626 (August 1956), "Radioactivity of Air and Fallout Samples Collected on the 80th Meridian," I. H. Blifford, Jr., and L. B. Lockhart, Jr.

(*f*) Supplementary monthly letter reports entitled, "Radioactivity of Air and Fallout Samples Collected on the 80th Meridian."

(*g*) Publication in Science, vol. 123, No. 3208, pp. 1120–21 (1956), "Collection of Atomic Bomb Debris from the Atmosphere by Impaction on Screens," I. H. Blifford, Jr., L. B. Lockhart, Jr., and R. A. Baus.

(*h*) Publication in Science, vol. 123, No. 3198, pp. 619–622 (Apr. 13, 1956), "Fallout Dosages at Washington, D. C.," by I. H. Blifford, Jr., and H. B. Rosenstock.

(*i*) Publication in Nature, vol. 177, pp. 990–992 (May 26, 1956), "Relationship Between Air Concentration of Radioactive Fission Products and Fallout," by I. H. Blifford, Jr., L. B. Lockhart, Jr., and R. A. Baus.

2. There is available some unpublished data on the subject of fission product concentration in the air at various sites along the 80th meridian which is being collected through a joint NRL-AEC-Weather Bureau program. An abstract of a report in preparation is attached (enclosure (1)). The gross measurements of the β-activity of the air are reported in NRL Memo Report 626 and subsequent monthly letter reports (enclosure (2)). Preliminary radiochemical analyses have been performed on a few weekly air filter collections of radioactivity from Peru, Guayaquil, Panama, and Washington. The results of these analyses are summarized in Table I. Sr–90 data are not available at present but will be included when the necessary low-level counting equipment is put into operation.

3. A single experimental collection at Washington, D. C., of "fallout" and "rainout" over a 2-week period has been analyzed and the results reported in table II. Other information is available in rough form on the gross β-activity (fission products) of collections made by the air-filter, cloth-screen, and gummed-film methods at several locations along the 80th meridian. A comparison of weekly averages of the relative gross fission product concentrations in the air at ground level at a number of locations along the 80th meridian is available which indicates that this activity is concentrated in the mid-latitudes of the Northern Hemisphere.

ABSTRACT

Measurements of atmospheric radioactivity and fallout at a number of sites along the 80th meridian (west) are reported for the year 1956. These results were obtained through the combined efforts of the United States Naval Research Laboratory and the Meteorological Services of Chile, Peru, and Ecuador with the cooperation of the United States Weather Bureau and the United States Atomic Energy Commission.

Radioactivity levels at the various sites during 1956 are reported for three different collecting systems: air filters, cloth screens, and gummed films. Extremely wide variations in the gross radioactivity of fission products in the air have been noted, with the highest levels occurring in the Northern Hemisphere. The presence of some of the peaks of activity at various localities has been correlated with known atomic explosions.

Radiochemical techniques are being developed for the routine analysis of collections for certain isotopes. Preliminary results of such analyses of a few filter collections indicate that the air at all of the collecting sites contains excessive quantities of the longer-lived fission products.

RADIOACTIVITY OF AIR AND FALLOUT SAMPLES COLLECTED ON THE 80TH MERIDIAN

By I. H. Blifford, Jr. and L. B. Lockhart, Jr., August 1956,
Naval Research Laboratory, Washington 25, D. C.

ABSTRACT

A brief review is given of the status of the project for collecting atmospheric radioactivity samples at various sites along the 80th meridian. Radioactivity data for the months of May and June 1956 are presented.

Problem status: This is an interim report; work on this problem is continuing.

Authorization: NRL Problem A02–13. Project No. NR 612,130.

In accordance with arrangements between the meteorological services of Chile, Equador, and Peru and the United States Weather Bureau, the United States Naval Research Laboratory, in participation with the United States Atomic Energy Commission, is supplying equipment for collecting fission product radioactivity in the air and as fallout. The collected samples are being returned to Washington, D. C., for measurement.

This report is a brief review of the status of the work as of August 1, 1956, and includes a summary of the radioactive assay of samples collected through June 30, 1956. Monthly bulletins will be provided in the future as promptly as possible after the measurements have been completed and the data tabulated.

The following collecting devices are being supplied: (1) small pumps and filter papers for sampling the atmosphere, (2) standard gummed paper fallout devices developed by the AEC, and (3) experimental collectors using cloth screens attached to wind vanes. Table 1 shows the status of each of the present and proposed stations. Supplies for approximately 3 months' operation were sent in

the initial shipment to each station and an additional 6 months' supply will be forwarded in August.

It may be of interest to note that NRL is operating radioactivity measurement equipment of other types at United States Naval bases in Hawaii, Japan, Alaska, and the Philippine Islands, and at Little America, Antarctica (in cooperation with the United States Weather Bureau). Similar measurements are being made in Brazil in cooperation with the National Research Council of Brazil. Preliminary data indicate that fission product radioactivity in the air at Little America was about 3 percent of that at Washington, D. C., during May and June 1956.

On receipt at Washington, D. C., each sample is ignited in a furnace at 700° C. and the residue assayed for radioactivity (assuming a beta energy of 1 MeV) using an end-window Geiger counter. Corrections for geometry and sample weight are made. No correction is made for the loss of volatile products upon ignition. In order to allow sufficient time for receipt of the samples and for the decay of the short-lived fission products and natural radioactivities, each sample is counted on the fourteenth day after collection.

The air filter results are given in disintegrations per minute (d/m) of fission product β-activity per cubic foot of air and are presented in tables 2 and 3 for all samples received for May and June 1956. The filter papers retain very nearly 100 percent of the fission particulates and have negligible natural radioactivity at the time of measurement. The airflow rate is 40 cubic feet per minute. Reduction in airflow due to plugging of the filter is negligible at this flow rate. The activities of individual filters having measurable radioactivity but less than approximately 0.0020 d/m per ft.^{3} are tabulated as *traces*.

The fallout measurements using gummed films are reported in disintegrations per minute of fission product β-activity per square foot and are given in tables 4 and 5. No corrections for the collection efficiency of the gummed films have been made. Unexposed films have been found to have no measurable radioactivity. The activities of individual samples containing radioactivity but with less than 40 d/m per ft.^{2} are tabulated as *traces*.

For the month of June 1946, the residue from the ignition of all of the gummed papers from each station was combined and a weighted fraction assayed for radioactivity on July 25, 1956. The total fallout radioactivity during June 1956 for each location is given in table 6. It is to be observed that the activity of the Guayaquil sample was extremely low and that it was not practical for it to be measured to the same accuracy as for samples from other locations.

The cloth screen results are presented in total disintegrations per minute of fission product β-activity and are given in tables 7 and 8 for May and June 1956. A correction has been made for a small amount of natural radioactivity in the unexposed cloth. The activities of individual samples containing radioactivity but with less than 40 d/m are tabulated as *traces*.

The tabulated values for samples collected over periods longer than 24 hours represent the total measured activity divided by the number of 24-hour periods in the collection. Days for which samples were not available have been indicated by a dash. The maximum counting error (standard deviation) is not greater than ±20 percent for any measurement. For the majority of the samples, the counting error is between 5 and 10 percent.

Subject: Radioactivity of air and fallout samples collected at sites on the 80th meridian during January 1957; NRL problem A02-13, project No. NR 612130; interim report on.

Figure 1: Daily record of fission product β-activity collected by the filter method.

Figure 2: Daily record of fission product β-activity collected by the cloth screen method.

Figure 3: Daily record of fission product β-activity collected by the gummed paper method.

1. Radioactivity measurements of air and fallout samples collected at various sites along the 80th meridian (west) during the month of January 1957 are presented in figures 1 through 3.

2. These measurements are being carried out as part of the United States Naval Research Laboratory program of atmospheric radioactivity studies. They are being made with the assistance of the Meteorological Services of Chile, Ecuador, and Peru and in cooperation with the United States Weather Bureau, Department of Commerce. Partial financial support is provided by the Division of Biology and Medicine, United States Atomic Energy Commission.

U. S. NAVAL RESEARCH LABORATORY,
Washington 25, D. C., March 29, 1957.

Subject: Radioactivity of air and fallout samples collected at sites on the 80th meridian during February 1957; NRL problem A02-13, project No. NR 612130; interim report on.

Figure 1: Daily Record of fission product β-activity collected by the filter method.

Figure 2: Daily record of fission product β-activity collected by the cloth screen method.

Figure 3: Daily record of fission product β-activity collected by the gummed paper method.

1. Radioactivity measurements of air and fallout samples collected at various sites along the 80th meridian (West) during the month of February 1957 are presented in Figures 1 through 3.

2. These measurements are being carried out as part of the United States Naval Research Laboratory program of atmospheric radioactivity studies. They are being made with the assistance of the Meteorological services of Chile, Ecuador and Peru and in cooperation with the United States Weather Bureau, Department of Commerce. Partial financial support is provided by the Division of Biology and Medicine, United States Atomic Eenergy Commission.

(Following is an article by Dr. Patterson and Dr. Blifford of the Naval Research Laboratory.)

[Reprinted from Science Magazine, March 3, 1957]

ATMOSPHERIC CARBON-14

According to Libby,[1] most of the neutrons which escape into the surrounding atmosphere from an atomic or thermonuclear explosion interact with the nitrogen of the atmosphere to produce C^{14} through the nuclear reaction.

$$N^{14}+n\rightarrow C^{14}+H^{1}$$

Because of the extensive use of C^{14} dating techniques, small additions of this material to the atmosphere may be important.

Libby[1] further estimates that, even to double temporarily the atmospheric radiocarbon content, megatons of fission of the order of 1000 would be required. With the measurement techniques now in use, it is possible to make measurements of the present equilibrium level of C^{14} in contemporary biological materials to an accuracy of approximately 1 percent. From these considerations it seems probable that only thermonuclear explosions will produce sufficient C^{14} to give measurable increases.

On the assumption that any C^{14} formed in weapons tests would be present in the air as CO_2,[2] collections of this gas from the atmosphere were begun in 1952. A vacuum pump was used to draw filtered air through a solution of sodium hydroxide (80 g of NaOH in 2 gal of water) at a flow rate of 10 to 12 lit/min. At the end of the collection period, the solution contained 15 to 20 lit of CO_2 as Na_2CO_3, which was precipitated as $CaCO_3$ by the addition of $CaCl_2$. The precipitated calcium carbonate was separated by decantation and filtration, was dried, and was placed in sealed containers. By drawing the air through two

2 W. F. Libby, Radiocarbon Dating (Univ. of Chicago Press, Chicago, Ill., ed. 2, 1956).

collecting bottles in series, the efficiency of collection of CO_2 from the air was found to be approximately 80 percent.

The counting technique employed was that developed by Suess,[3] in which the carbon-containing material is converted first to carbon dioxide and then to purified acetylene. The acetylene is used as the counting gas in a well-shielded proportional counter with an anticoincidence arrangement for reducing the cosmic-ray background. It was found that excellent stability and good repetitive accuracy could be obtained over periods of a year or more.

We were fortunate[4] in obtaining small quantities of strontium carbonate prepared from fossil carbon (lignite coal) and from contemporary carbon which had been measured previously.[5] These samples were converted to acetylene and served as standards for all of our measurements. For each of the experimental values reported here, the counting rate of the atmospheric carbon was compared with two measurements on the contemporary carbon standard and with two measurements on the fossil carbon standard. One standard measurement was made within 3 days before, and the other within 3 days after, the sample count. In some cases, the reported values were derived from more than one measurement, and in other instances two completely separate samples were prepared from the same atmospheric carbon. All of the errors shown were computed from the total number of counts and are expressed as the 9/10 error in this quantity.

In order to test the reproducibility of the entire process, three simultaneous atmospheric carbon samples were collected and separately processed. The counting rates obtained were well within the expected statistical error.

By means of the afore-described techniques, four 1-week samples collected during the period from October to December 1952 in French Morocco and four similar collections in Alaska gave average values for the sample/standard ratio of 0.97 ± 0.01. Four samples collected at Washington, D. C., during this same period gave an average of 0.95 ± 0.01, while three collections made in the Hawaiian Islands and three in the Philippine Islands gave average sample/standard ratios of 1.00 ± 0.02. In no case did the C^{14} content of the atmospheric sample exceed that of the standard. The lower values (particularly at Washington, D. C.) are believed to reflect the dilution effect of the burning of fossil fuels.

[3] H. E. Suese, Science 120, 5 (1954).

[4] We wish to thank M. Rubin, for supplying the standard samples; L. B. Lockhart, Jr., H. Friedman, and R. A. Baus, for helpful discussions; Paul Gustafson, who assisted in the preparation of some of the samples; and the Naval personnel who collected the CO_2 samples.

[5] H. E. Suess, Science 122, 415 (1955); the sample of contemporary carbon was prepared from wood grown before 1900 and was sample number W-214, Table 1, of this reference.

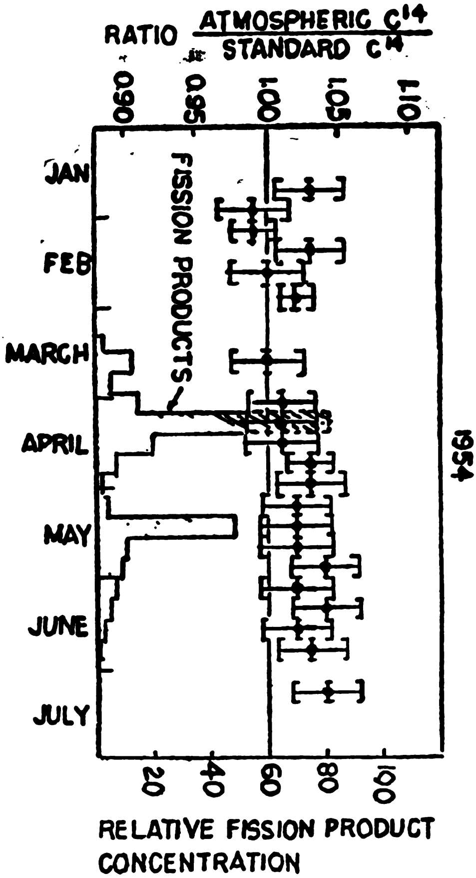

FIG. 1.—C^{14} content of atmospheric CO_2 samples collected at Subic Bay, Philippine Islands.

We were able to obtain CO_2 collections from the Naval station at Subic Bay in the Philippine Islands during the thermonuclear tests of 1954. They are of interest, since it was possible to measure simultaneously the ground-level concentration of fission products. The direction of the winds below 20,000 feet from the Pacific proving grounds was such that the observed radioactivity should have been the result of low-altitude fission debris. The counting rates of atmospheric carbon, referred to standard carbon, for CO_2 samples that were collected from January to July of 1954 are illustrated in Fig. 1, along with the relative fission-product concentration for the same period. It is clear that the concentration of C^{14} did not increase as markedly as did that of the fission products. However, it does appear that it was somewhat higher after the tests than at the time of the 1952 collections. It is possible that most of the C^{14} which was formed was entrained in the hot gases of the fireball and injected into the stratosphere so that relatively little was present in the ground-level cloud.

In Fig. 2 are shown the relative atmospheric/standard carbon counting rates from collections made in Washington, D. C., from January 1955 to February 1956. Samples collected in the months of May through November 1955 were significantly higher than the standard in C^{14} content and, in one instance, as high as +18 percent. The fact that the concentration was at a minimum during the colder months may indicate a seasonal decrease, resulting from reduced plant transpiration and the burning of fossil fuels. Almost all of the measurements gave higher values than those of October-December 1952.

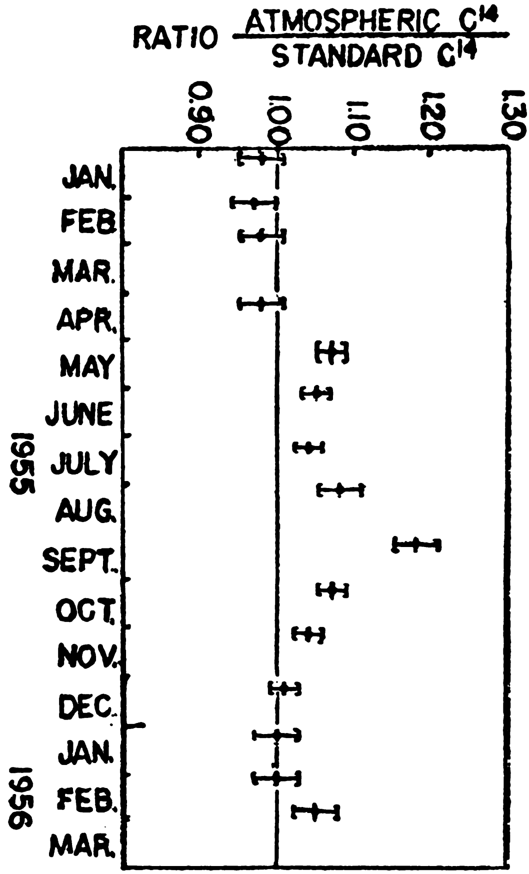

FIG. 2—C^{14} content of atmospheric CO_2 samples collected at Washington D. C.

Previous measurements of atmospheric C^{14} by Kulp[6] indicated no significant deviation from contemporary wood for 12 samples collected under a variety of conditions. Rafter,[7] on the other hand, found that four CO_2 samples collected in New Zealand in 1954 and 1955 had higher concentrations of C^{14} than had contemporary wood (+4.7 percent for one sample). Our collections at Washington, D. C., during the summer of 1955 gave values for the C^{14} content of atmospheric CO_2 appreciably higher than those previously reported. It seems difficult to account for these high values on the basis of isotopic fractionation, and therefore the increase in the C^{14} content of atmospheric CO_2 from 1952 to 1956 is probably the result of the addition of radiocarbon from thermonuclear sources. The delayed appearance of the C^{14} increase at ground level may indicate a stratospheric reservoir of this isotope.

STATEMENT OF DR. J. L. KULP, COLUMBIA UNIVERSITY AND DIRECTOR, LAMONT GEOLOGICAL OBSERVATORY[2]

Dr. KULP. Thank you Mr. Chairman.

With Dr. Eisenbud's permission, I would like to use two of his charts.

In my opinion, the strontium 90 problem can best be divided into three phases. Phase 1 is the definition of the present level of strontium 90 in human beings.

The second phase is the determination of the factors which bring about this particular level, because, as we determine these factors, it then becomes possible for us to predict for any given future situation how much man will get into his body.

The third phase of the strontium 90 problem is the biological aspect of exactly how much injury will occur from various levels of radiation.

Since 1953, we at Columbia University have been engaged in a research project sponsored by the Atomic Energy Commission, in which we have been addressing ourselves to the first two of these three phases, and it is of these two that I wish to speak this morning.

Primarily, I will be speaking about phase 1, namely, the present level of strontium 90. I will have a few things to say about the distribution factors, but Dr. Eisenbud has already covered much of this.

Now, to set the framework for this discussion, I would like first to write down these units again.

In terms of micromicrocuries of strontium 90 per gram of calcium 1,000 is the present accepted maximum permissible concentration for an industrial worker. It is recommended that for populations that this be a hundred micromicrocuries.

The reason I would like to put these down at the outset is that we will continually refer to the levels in man, various men, various ages, in various countries, relative to these numbers. So we need to have them clearly in mind.

The 1,000 value is the industrial level that is now accepted by the National Committee on Radiation Protection, and the 100 value is the recommended level for population.

Our study to date has involved the analysis of about 1,100 human bone samples. These human bone samples have come from 25 stations all over the world and range over a maximum of geographical and dietary types. These localities range from Chile to various places

(Submitted by Witness.)

in the United States, Japan, Taiwan, India, and various sites in Europe.

I would like to break down the discussion of this data as follows:

First, to mention the age distribution for a given locality; secondly, the current levels, the current world average levels; thirdly, the change of these levels with time; fourthly, the change with geographical locations; and finally, the change with diet and other factors.

First, then, the age distribution.

For any given locality, whether it be New York City or Santiago, Chile, if we plot the strontium 90 concentration against the age we observe that there is a peak at approximately 5 years which then falls off and is level from 20 years through 60 and there is an indication of a slight increase above 60 years. So we may divide this curve essentially into these important parts:

Part A represents the beginning of equilibration of a young child with his diet. Bones are being formed rapidly in this range of zero to 4 years, and the child is getting most of his calcium from milk, at least in western civilization. The child is nearly in equilibrium with the milk of his diet.

Secondly, there is a period of dilution where from 4 years to maybe 20 years you are still building a certain fraction of the calcium into your bone. Thirdly, you have the average adult range, where essentially we are not building much calcium. So the uptake from strontium 90 is about the same whether you deal with a 25-year-old or 60-year-old person.

Then, due to various physiological processes for very old people there seems to be a very slight increase due to bone turnover. But this is the general pattern you get no matter what locality you are dealing with.

This curve will be shifted up and down depending on the fallout and the diet at that particular locality.

The difference between the young children and the average adult is about a factor of 7 or 8 in most cases.

Now, I wish to confine most of my remaining analyses to these two groups.

These data [indicating] refer to the adults, the 20 to 60 group, which are quite consistent everywhere we have studied, and the young children, zero to 4, because these are closest to the equilibrium with the diet. The children therefore give us the best measure of what the whole population will reach some day. Quite clearly this level will continue to rise as the bones of adults equilibrate with the environment, but they are doing it very much more slowly because of the large dilution of the dead bone which we have in our bodies pre-1954.

Next, what the are current levels worldwide?

The current levels for people who died in 1956 are as follows:

For the world, we have 2 categories, zero to 4, and the 20 to 60. We will consider the world, the North American average, and Chile.

The reason we use Chile rather than a South American average is simply at the moment we have a very large number of samples from here. So the statistics are good.

These results, based on approximately 400 samples, range as follows: 0.52; 0.70; 0.21; 0.08; 0.09; 0.04.

Now you will see immediately two things:

There is a factor of 7 or 8 between the children that are nearly in equilibrium, and the adults, you see, in North America are higher than the world average. Also North America is higher than Chile by about a factor of 4.

This is a very important fact because the difference between North America and Chile in the actual content of human bone is only different by about a factor of 4, or in the case of adults about a factor of 2. Yet is is quite clear from the soil data and the gummed paper data which Dr. Eisenbud presented that there may actually be a factor of as much as 5 or 10, in terms of fallout, between Chile and New York.

What are the reasons for this discrepancy?

The reason is that in our mechanized modern society, we bring food from considerable distances, and so the food tends to be pooled, and a particular single soil sample may not be representative at all of what the population is eating in that area.

A much more significant measure of what they are eating is the measurement of the milk consumption, as Dr. Eisenbud's laboratory has so completely done.

So we find that the geographical distribution is much more uniform than we might expect, and this is somewhat in disagreement with the emphasis of Dr. Machta yesterday of the differences between various places in fallout, but this is again a second order effect.

Next I would like to say something about the change with time.

We have a number of measurements which show the gradual increase of strontium 90 in human bone as time has proceeded from 1953 to the present.

I would like to give simply three illustrations of this.

The first illustration is that of New York City adults. In 1953, the average was about 0.04. In 1954, it was 0.07, and in 1955, it was 0.11, and in 1956 it was 0.13 micromicrocuries per gram of calcium.

So you see again, this general increase. However, as you note, this increase may be a factor of 3, whereas the milk shows a larger factor, posibly of 6. This is due, in part, I think, to this lag of equilibration, that is, the equilibration does not quite keep up with the change in the diet.

If we take quite a different case, that of Swiss children, in 1955 we find a considerable change, although the number of samples is limited to about a dozen, going in 1955 from 0.50 to in 1956 1.02. This again is for the zero to 4-year-olds.

Finally, to illustrate the change with time, I would like to take world averages for all children zero to 4 and compare 1955 with 1956:

In North America, 0.57 to 0.70;

In South America, 0.27 to 0.38;

In Europe, 0.40 to 0.42.

The overall worldwide average rose from 0.43 to 0.52.

This is the world change from 1955 to 1956, and it essentially means a 20-percent increase in the worldwide average from 1955 to 1956.

How do we explain this?

There is a considerable lag, of course, between the concentration of strontium 90 in the body and the time strontium 90 falls out. It is observed that in 1954 and 1955 the curve did not change; it is almost level. This was due in part to a very large increase in the Castle tests

of 1954, and then a leveling out. So this difference of only 20 percent is reflecting in part this rather level period.

Actually we do not have any measurements on children that are anywhere near equilibrium with this number.

One further word about geographical location.

The main thing to be said about geographical location, I think, is the amazing uniformity, the striking uniformity worldwide. Of our 25 stations, the maximum difference is a factor of 3 between the average zero to 4 children, let's say, in Chile and, maybe, Zurich, Switzerland. So that the maximum range in urban centers is very much less than the range in total fallout.

One other point on geography regarding the chairman's question to Dr. Eisenbud on Japan, and that is the average for Japanese children away from the atom-bombed area, is somewhat lower than the United States, consistent with the lower soil and fallout information.

Now let us consider the distribution around the mean.

It has been pointed out by a number of scientists that simply giving these average values does not tell the whole story, because even though the average value for children in North America, 1956, is only seven-tenths of a unit as compared to 100 units, nevertheless there is a question as to what is the distribution around this mean.

Clearly, if the distribution is very broad, then you may have an appreciable number of children that are very much higher than this. Therefore, I would like to consider what this distribution actually looks like, and what are the reasons for this distribution.

In order to do this, I would like to plot 2 curves, 1 for Swiss and Boston children, and 1 for German and British Columbia adults.

Chairman DURHAM. Do you mind a question at this point?

Dr. KULP. No, sir.

Chairman DURHAM. I believe yesterday we had evidence, of course, that the actual fallout of strontium 90 was nonuniform.

Dr. KULP. Right.

Chairman DURHAM. As I read your statement there, and analyze it, it is the fact that the analysis is uniform to a certain extent.

Dr. KULP. It is more uniform.

Chairman DURHAM. How is that?

Dr. KULP. It is more uniform.

Chairman DURHAM. More uniform?

Dr. KULP. Right. And the reason for this, I believe, is that, as we have shown in some independent experiments at Columbia, virtually all of the fallout comes down with rain, and you do not grow agricultural crops in a desert. So this helps to equalize the situation. Secondly, foodstuffs are transported great distances. Even some South American countries eat some wheat produced in Canada.

Senator ANDERSON. Doctor, your statement that you do not grow agricultural crops in the desert. Are you at all familiar with irrigation?

Dr. KULP. Yes, sir.

Senator ANDERSON. Do you know whether or not the State of California has moved ahead as one of the largest of the agricultural States, and, roughly, about how much of the agricultural produce of California comes from irrigated areas in Fresno, Salinas, and places like that?

Dr. KULP. Yes. I was coming to the point, if you will give me just a minute.

Senator ANDERSON. As long as you have it in mind.

Dr. KULP. This, of course, is largely truck farming, and other vegetables and fruits, rather than wheat.

Senator ANDERSON. People eat this so-called truck, do they not?

Dr. KULP. Oh, yes. I wish to come back to this point. It is a rather interesting one, and it shows something quite unexpected and quite favorable.

Senator ANDERSON. You said you were going to deal with some Swiss and Boston children, and some German and British Columbia children?

Dr. KULP. Adults.

Senator ANDERSON. Adults?

Dr. KULP. Yes, to look at the distribution around this mean we are talking about.

Senator ANDERSON. We will get to the point later sometime, but did you make a study of bones in British Columbia?

Dr. KULP. Yes, sir.

Senator ANDERSON. Did you find one of those that had very much greater deposit of strontium 90 in his bones than was normal?

Dr. KULP. Yes, sir.

Senator ANDERSON. Seventy times as much?

Dr. KULP. Yes, sir.

Senator ANDERSON. Did you discard that sample?

Dr. KULP. We did not discard it. We looked at it with a jaundiced eye, because the sample was measured in the very early stages of the work, and it was an extremely small sample.

Senator ANDERSON. A jaundiced eye is a diseased eye. [Laughter.] Why not look at it with a good eye?

Dr. KULP. A critical eye might be a better statement. The fact of the matter is——

Senator ANDERSON. Why not look at it with an impartial eye?

Dr. KULP. Impartial or critical is fine.

Senator ANDERSON. But they are not alike, are they?

Dr. KULP. Impartial and critical?

Senator ANDERSON. Are they exactly alike? Well, never mind. I am only hopeful we might look at it with an unprejudiced eye. Put it that way.

Here is a sample that is 70 times greater——

Dr. KULP. That is right.

Senator ANDERSON. Than any other sample you have had. So you say, "We will throw that one out."

Dr. KULP. No. I am very careful not to say we throw it out.

Senator ANDERSON. What do you do with it?

Dr. KULP. In our scientific report, the first report of this data, we were careful to include it.

Senator ANDERSON. Did you evaluate it fully or give it a smaller rating than something else?

Dr. KULP. No. It was clearly stated as a particular determination, and it was pointed out that although there is always the possibility of a single determination being in error, there is also the possibility, since we are dealing with the statistical phenomena, that this might be

a real high number. It seems very unlikely as more data has amassed, because we get nothing else like this with better samples and better techniques and the diet of the North American would not include anything that we know of that would lead to such a high value in an individual. Nevertheless, we cannot dismiss it, because we have checked back with the laboratory notebooks, and there is no excuse for throwing it away.

Senator ANDERSON. Of course, when the atomic bomb fell on Japan, they had never seen anything like that, either.

Dr. KULP. That is right.

Now, if I may proceed with these two distribution curves.

First, we will have the Swiss and Boston children. Interestingly enough, these two groups of children in 1956 have identical averages, and almost identical distribution curves.

We have the number of cases on the vertical ordinate and the horizontal obscissa is the strontium-90 in the units of micromicrocuries per gram of calcium.

Now, the distribution curve looks something like this (fig. 1). In other words, the initial portion of the curve is a very normal symmetrical sort of a thing. It has a peak at around 6 of these units, and it comes down to about 1.2. Then there are a few samples up as high as the highest value of 2.2.

Now you get the identical curve from both Boston and Zurich. The age distribution is from zero to 9 years here. So far as we can tell there is nothing unusual about either locality.

Now I would like to superimpose on this the curve for these adults, which is quite different in character, and then I will try to explain what I think is the reason for this difference (figure 2).

(The graphs referred to follows:)

Dr. KULP. The adult situation is closer to this on a different scale. The horizontal scale extends to about 0.2 instead of 2.

The reason for these variations are due to three sources: First, differences in diet.

This tends to be averaged out in a metropolitan community.

Secondly, you get some slight differences, due to age, but this is restricted here to 9 years.

But finally, the most important reason for variation of this kind is due to individual variations among the bones of the body. For example, if you take 2 ribs, 1 rib may have as much as twice the strontium 90 as another rib in an adult. In a child you do not get as much variation, because the child is almost in equilibrium. In other words, every bit of bone that is being built is very similar to the next bit of bone as far as the strontium 90 to calcium ratio is concerned. Whereas in an adult you may have a large section of bone which is not active at all, another section where it is quite active. So if you were to break up the bone, you would find an irregular distribution of strontium 90 in the bone.

We have done quite a few studies in an attempt to see what this variation is like, and we find that in children the variations from one bone to another generally do not exceed maybe 20 or 30 percent. Thus, we would expect a more symmetrical and narrower distribution in the case of children than in an adult.

You see the mean here is 0.6. Then the distribution around the mean is only about plus or minus 50 percent.

In the case of the adults, however, you have this large variation from one bone to another, and thus you observe a symmetrical curve. The mean develops a tremendous tail (see figure 2), due to the large variations from one bone to another.

The conclusion we draw from this is that it could be more desirable to analyze whole skeletons which we are now doing in 200 cases in 1 locality. Obviously in this sort of business it is difficult getting the proper samples. But in view of the fact that even the Atomic Energy Commission or the contractors cannot indulge in grave-robbery, it is not possible everywhere in the world to get the whole body sample, which is the ideal sample. Thus we must take the individual bones and understand how much they vary.

We believe that the variation is quite narrow for a given locality, and that the variation we are observing in the adults is largely due to variations from one bone to another.

We conclude, then, that so far as the present concentration of strontium 90 in man is concerned, that in urban populations the spread is very narrow; that it probably does not greatly exceed the normal variation in ordinary strontium to calcium.

Next, I would like to say just a little bit about the cycle of strontium 90, in particular with reference to some original work which we have done at Columbia.

In the past year we have measured all of the rains which have fallen in the area, and we have calculated the strontium 90 fallout per square foot as brought down by rain. We have also computed by measurement the strontium 90 per square foot that has been added to the soil of the New York area.

These two numbers agree rather well, and indicate that during the last year or year and a quarter about 10 millicuries per square mile

have come down. About three of these are probably due to stratospheric drip, and much of the rest is due to Russian testing. At least we did not report any testing during that period.

The present level in the United States——

Senator ANDERSON. So that a third is from what has been tested previously, and two-thirds came from the recent tests of the Russians?

Dr. KULP. Apparently, or at least half. Let's be more conservative, and say at least half in the last year seems to have come from tropospheric fallout from Russian testing.

Senator ANDERSON. You used the figure of a third of it came from drip, you said, from the stratosphere.

Dr. KULP. Yes.

Senator ANDERSON. And you thought the rest was from the Russian testing.

Dr. KULP. We did obtain from some carryover, probably, from our own testing.

Senator ANDERSON. Is not that important to us, to try to evaluate that also?

Dr. KULP. Yes.

Now, the next thing that we should point out, is that the average in the United States at the present time is, say, 25 to 30 millicuries per square mile, as Dr. Eisenbud has shown here; and that at the present rate of drip from the stratosphere we are adding a little bit more. If there is no more testing, we are adding a little bit more strontium 90 than is decaying away.

Senator ANDERSON. That is somewhat important. You say if there are no further tests, the present rate of drip would give us a little more strontium 90 than is decaying away?

Dr. KULP. For a time. And then eventually——

Senator ANDERSON. Well, can we state that for the present, at the present time that is happening? So that if there is testing going on, we are substantially adding, then, are we not, to the amount of strontium 90?

Dr. KULP. That is correct. Before finishing, I would like to compare these figures of varied predictions.

Senator ANDERSON. The statement has frequently been made, that we would be all right if we could keep a balance between the strontium 90 coming down to us from the stratosphere, plus the carryover from our previous tests, plus current testing as against the rate of decay.

Dr. KULP. Right.

Senator ANDERSON. And if we are not adding to it at any greater rate than the rate of decay we were all right. We were in balance. But it is your testimony that if we do not test any more, we will still have a greater drip, as you call it, than the rate of decay?

Dr. KULP. Slightly greater; yes.

Now, the next thing we must do is to examine what these discrimination factors are in going from the food all the way to man.

Representative HOLIFIELD. At this time, Dr. Kulp, I am going to ask you to look over the transcript, after you have received it, and prepare the charts you are referring to, so that we can have copies of them, and have them printed in the record at the appropriate place.

Dr. KULP. Yes.

Representative HOLIFIELD. Otherwise, your testimony in referring to these charts which you write on the board and the rates, will not be included.

Dr. KULP. Let us consider vegetation in general, for a moment. There are two routes of strontium 90 in vegetation to man. One route is through fodder to the cow, and then to the man through milk. Discrimination against strontium 90, considering strontium 90 per gram of calcium—the discrimination against strontium 90 in this step is about 7. The discrimination against strontium 90 in going from fodder to the cow's milk is a factor of about 7, as determined by Dr. Comar of the Oak Ridge Institute, and several other workers. The discrimination from cow's milk to man's bones appears to be about 2.

Senator ANDERSON. Can we understand what a factor of about 7 means?

Dr. KULP. It means that the strontium 90 per gram of calcium is 7 times less in the cow's milk than it is in the feed for the cow; and it means that the strontium 90 per gram of calcium in deposited human bone is half what it is in the milk which the human consumes once the human is at equilibrium.

Now, there is another route through which strontium 90 can come to us from vegetation, and that is our other direct vegetable sources. Meat contributes very little strontium 90. Drinking water contributes very little. But we can get, in principle, detectable and significant amounts from other sources of food.

Just within the last 6 months, we have begun a measurement program, attempting to analyze all varieties of frozen foods, such as those which come from the Imperial Valley of California. Somewhat to our surprise, we found that the strontium 90 per gram of calcium is very much lower in these vegetables than in fodder.

Reflection on this, of course, made us realize that the cow's fodder by and large consists of grasses that utilize the top few inches of soil, whereas the truck-farm vegetables commonly have deeper roots and, furthermore, the truck farms are very carefully nutured and calcium is added to the soil. So whereas the cow's fodder is now on the order of 40 to 50 micromicrocuries per gram of calcium [indicating], and the milk is on the order of 5, the truck-farm vegetables are averaging about 6. It turns out that when you eat these kinds of vegetables, the discrimination is not 2, as it is with milk, but fortunately it is 4. Therefore, at the present time, about 80 percent of the child's calcium comes from milk and dairy products, and at least half of the calcium of the adult comes through this route, even for a real coffee drinker, nevertheless, almost all of the strontium 90 is coming via this route [indicating].

If, however, the truck farm vegetables were as high as the grasses, then the vegetables would be our major source of strontium 90.

Actually our main strontium 90 source is milk and milk products [indicating], even though it is discriminated against by a factor of 14. Most of the strontium 90 is coming from this route [indicating].

Representative HOLIFIELD. How does this pattern differ when you consider vegetation and vegetables and fodder and intake and uptake and so forth, from an area where it has plenty of rainfall as compared to an area that is irrigated, such as Imperial Valley? Is there a difference?

Dr. KULP. Actually, the Imperial Valley, for the same kind of vegetable, would be a lot lower.

Representative HOLIFIELD. You say a lot lower. Have you tested vegetables in milksheds, the New York milkshed, for instance; New Jersey? There are a lot of vegetables raised there, and I think they depend more on rainfall than they do on irrigation.

Dr. KULP. This program is only begun, but we have about two samples from the irrigated area of California, and we have several from Maryland, some of the Maryland truck farms. And the California ones are lower. But both of them compared to the milk are lower.

Representative HOLIFIELD. In other words, the milk is higher in the rainfall areas and the vegetables are higher in the rainfall areas. Do you have enough data in order to give us what the degree is instead of the word "lower"? Do you have enough data?

Dr. KULP. No; I do not think we have enough data to say anything beyond that it may be as much a factor as 5 lower.

Representative HOLIFIELD. In another statement we have here, the rainfall data for Brawley, which is in Imperial Valley, in 1955 was 1.70 inches. You see that is very low. I suppose in this area it would be around 40, maybe 45, would it not?

Dr. KULP. Yes.

Representative HOLIFIELD. And the rainfall does bring out of the atmosphere, according to your own testimony—it is the primary factor in bringing down radioactive particles, prime particles. There would be a sharp difference, I would suppose.

Dr. KULP. Yes; and this is the reason Dr. Eisenbud was saying why you can get extremes on the low end, but you do not get any extremes on the high end. The maximum fallout, due to the 40 to 60-inch rainfall, is up to 100 or 150, which is only a factor of 2 higher than the average. But you can go down an inch or less than an inch of rainfall in desert area which is lower by the factor of 40.

The next thing I would like to do as far as strontium 90 in man is concerned, is stick my neck out on a few predictions.

Again I would like to refer to these values——

Representative HOLIFIELD. When you say "these values," the record will not show what you mean.

Dr. KULP. The thousand micromicrocuries of strontium 90 per gram of calcium for the industrial permissible level, and the 100 which is recommended for general population.

As far as adult man is concerned, in 1956 he has about one-tenth of a unit, which is 1,000 times less than this 100, or whatever the experts will make it this next week. Our job is to try to determine what is there.

Secondly, the children, worldwide, in 1956, are about 0.5 and in the United States about 0.7.

I would like to divide this now into two groups because we will predict both for the United States and for the world.

So far as the United States is concerned, the present children are about 0.7. The average world is about 0.5, with, of course, Chile being lower than that.

Now, let us ask a question. We know these are not in equilibrium. The first question is: If there is no more testing, and everything comes down, and we all reach equilibrium, what will these numbers look like? My prediction is they will be about 3 and 1.

Chairman DURHAM. When? What date?

Dr. KULP. Within 10 years.

Senator ANDERSON. That jumps from 0.7 to a full 3?

Dr. KULP. Yes. This is not because we are waiting for three times as much to fall out; we are waiting for equilibrium.

Senator ANDERSON. That is based on no more testing?

Dr. KULP. Correct.

Senator ANDERSON. Just so we can see where we might go, how many years did you say that would be—5?

Dr. KULP. Five to ten years, as we approach this [indicating].

Senator ANDERSON. If instead of there being no more testing, you would make a graph of the growth of testing, and how to apply that to the figure of 3, what would you bring it to—30?

Dr. KULP. I would prefer, if you let me take the next step, which is to say what will these numbers be if the present rate of testing continues.

Senator ANDERSON. And then from that we can interpret what it might be if the curve moved up?

Dr. KULP. Yes.

This is "no testing."

The next step is: What if every 5-year interval from now on we have the same amount of testing we have had in the last 5 years? The numbers then come up to 24 and 8.

Senator ANDERSON. Are we to read that in connection with 100?

Dr. KULP. Yes.

Senator ANDERSON. So they would have a fourth as much?

Dr. KULP. Right.

Senator ANDERSON. If we happen to have acceleration of tests, as we are now doing, and the British get into the picture and the French and the Italians, and the Germans and everybody else, it would only take a very few years, 3 or 4 at the most, to get that up to the 100, would it not?

Dr. KULP. I think anyone can calculate from here for any predicted rate what it would be.

Senator ANDERSON. I was going to try to give a scientific guess, and I was going to have my own curbstone opinion. But, in any event, if it is going to come to 24 if we keep up the present rate of testing, we freeze it at the present level, and we know we are moving faster, we know it is going up to whatever the maximum permissible level is for children?

Dr. KULP. Right.

Senator ANDERSON. Thank you.

Representative HOLIFIELD. Let me understand. When do we get to the 24—in 5 years, is it?

Dr. KULP. No.

Representative HOLIFIELD. In how many years?

Dr. KULP. This would probably require 50 to 60 years at the present rate—every 5-year interval there is the same amount we have had in the last 5, and we keep on with this. Then in the year 2010, or something like that, we come up somewhere near these values.

Senator ANDERSON. If the rate is frozen for 6 years, we come up with the rate of 24, but if the present rate of acceleration continues——

Dr. KULP. One can make his own computations.

Senator ANDERSON. Wet get to a hundred in a very few years. Depending on one's own calculations. That is right. One man's guess is about as good as another's.

Dr. KULP. I do not think it is a guess. I think we have enough data now so we can predict within a factor of 2 what will be for any set of circumstances.

Senator ANDERSON. Has not someone fed this into the "Maniac" out at Los Alamos or a calculating machine somewhere else, to have it say if the rate of increase in testing—with the way these new countries are getting reactors under the Atoms for Peace program, and if they all get in the game, if we calculate all this new increase, all these new reactors coming in, and so forth, has not somebody tried to make a calculation?

You had to use a little bit of mathematics to make the calculation of 24 in 6 years. What happens if we increase at the same rate we have been increasing in the last 5 years in testing? Has anybody tested that or calculated that?

Dr. KULP. I do not know. I have not.

Senator ANDERSON. I would suppose there would be somebody that would feed it into one of these mechanical brains and try to see what it comes up with.

Dr. KULP. You will have to ask the Commission that, I think.

Senator ANDERSON. We will ask somebody that. You have not, in any event?

Dr. KULP. No.

Senator ANDERSON. It would not be in your field of competence?

Dr. KULP. Overall, it is not a difficult thing to do once basic perimeters are established.

Senator ANDERSON. I would not think so. I would think you would have all the information necessary for someone to drop it into a calculating machine and get the answer.

Dr. KULP. I would like to conclude these points——

Representative VAN ZANDT. May I ask several questions at this point, Mr. Chairman?

Dr. KULP. Yes.

Representative VAN ZANDT. In October 1956, Dr. Libby said that United States children will eventually accumulate up to 1 percent of the maximum permissible concentration of strontium 90.

Do I understand that this point 7 you have on the board is seven-tenths of 1 percent of the maximum permissible concentration?

Dr. KULP. Correct.

Representative VAN ZANDT. Then the numeral 3 there represents 3 percent?

Dr. KULP. Right.

Representative VAN ZANDT. And the 24 represents 24 percent of the maximum permissible concentration of strontium 90?

Dr. KULP. Correct.

This data is not in sharp disagreement with Dr. Libby's statement, because a year ago we would have predicted, maybe, 1½ here instead of 3. The reason it is 3 rather than 1 is simply because the Russians are quite active and more things have happened. His calculations were based on what had fallen out as of early 1956.

Representative VAN ZANDT. Dr. Kulp, you have described the routes by which strontium 90 can reach the human body, through vegetation and through milk?

Dr. KULP. Yes.

Representative VAN ZANDT. What about the human body absorbing the radiation from that which is breathed into the lungs?

Dr. KULP. This has been studied rather carefully by other groups than ours. You can probably get more of this information from the men next week. But the conclusion has been that the inhalation hazard is definitely negligible compared to the ingestion hazard.

Representative VAN ZANDT. What about the particles settling in a man's hair?

Dr. KULP. Trivial.

Representative VAN ZANDT. What about the particles settling on the inside of a man's clothing?

Dr. KULP. Trivial.

Representative VAN ZANDT. So the only way that he can really get a dose of strontium 90 is through the milk?

Dr. KULP. Right.

Representative VAN ZANDT. Or eating the vegetables?

Dr. KULP. Right.

We have not discussed maximum man, and this is a very difficult problem, but it is also a very important one, probably in the overall philosophical consideration of this subject.

We have talked about average man, we have talked about the distribution curve for people living near cities, but we do not have any samples that might approximate maximum man.

We have already said in our earlier discussions that the greatest variation of curves is due to the variation in the calcium content of the soil. Therefore, if we were to imagine a primitive culture where the calcium content of the soil was extremely low, and where the people of that area ate food which they grew only on their own half acre, then these people might be very much higher than anything we have been talking about here. However, they would have to be quite primitive.

Even in areas of North America they bring in appreciable food, but there are some obscure Indian tribes, of course, in the upper Amazon, that might very well live on food from their own village area. And this is where maximum man would be found, but nobody has the samples yet.

This variation is not due to differences in fallout; it is due to differences in the calcium content in the soil, and the lack of mixing of food products.

I would conclude, then, as far as the technical remarks are concerned, that, first, the current levels in man are fairly well defined, sufficiently well that I believe that, given any set of circumstances you wish to predict for the future, it is possible to compute within fair accuracy, say at least a factor of 2 or 3, what the levels in average man will rise to.

The distribution curve for modern urban societies is very narrow and, therefore, it is practical to talk about the average value of these measurements.

Much of the variation, apparently, can be due to the variation within the bones.

Chairman DURHAM. Doctor, that statement is based on the known amount of strontium today which exists?

Dr. KULP. Right. And we do not have the samples of maximum man. But certainly this cannot be represented by more than a very, very minute fraction of the world's population.

Finally, Mr. Chairman, if I might add 1 or 2 words as a citizen, rather than a scientist, for the record I would like to note three things:

First, that I do not think the difference in the opinion of scientists, such as Dr. Libby and Dr. Pauling, are anywhere near as great as some of the newspaper accounts would lead us to believe. I believe that as far as scientific data is concerned, they are probably in rather close agreement.

Dr. Libby has carefully said, or has pointed out that he is not saying there is no risk, and Dr. Pauling has admitted that the amount of radiation from strontium 90 is a very small fraction of the natural background. On these basic facts all are agreed.

Secondly, I would like to mention that I feel the whole problem of worldwide fallout from testing is completely trivial compared to the rather seemingly inevitable problem and continuing hazard of nuclear warfare.

Finally, I would like to emphasize that, if we assume that there is no threshold for bone cancer or leukemia, as some scientists now feel is probable——

Representative HOLIFIELD. What do you mean by "no threshold" please, for the record?

Dr. KULP. I mean that no matter how little radiation there is, there is some effect from it, that the number of cases are linear, or nearly linear right on down. This, of course, is what Dr. Pauling was using in one way or another in computing his number of deaths.

One can get quite different numbers, depending on assumptions, but philosophically there is no difference because if you admit there is no threshhold, there certainly are some deaths, and whether there are a 100 or 10,000 seems very irrelevant philosophically.

The point I wish to make is this: All of our environmental measurements, all of our models for the reactors, and the entire utilization of isotopes are based on maximum permissible concentration. That is, when we say the effluent from an industrial plant using atomic energy, the effluent in the river water must be below a certain value, that is set so that if a person drank that river water for the rest of his life, he would not exceed this MPC.

Representative HOLIFIELD. You are pointing to the top one now?

Dr. KULP. I am pointing to this—or this. No.

Representative HOLIFIELD. Please say it.

Dr. KULP. I think actually it is geared to this [indicating].

Representative HOLIFIELD. Now will you clarify your remark for the record so we will know what you are pointing to?

Dr. KULP. My point is that the present maximum permissible concentrations which are allowed for air, water, and soil in terms of disposal are maximum permissible concentrations calculated, such that a person living in an area and consuming that water and breathing that air for the rest of his life would not exceed the maximum permissible level of strontium 90 in the general population.

Representative HOLIFIELD. Which is?

Dr. KULP. One hundred micromicrocuries of strontium 90 per gram of calcium.

Representative HOLIFIELD. Fine.

Chairman DURHAM. Up to 70 years old, and then the rest of his life?

Dr. KULP. Yes, sir; the rest of his life.

Representative HOLIFIELD. That is from that one source.

Chairman DURHAM. No.

Dr. KULP. No; this is from any industrial application.

Representative HOLIFIELD. I understand. But you are applying it to that one source. That does not take into account how much he might get from other sources. You are referring it to the one industrial effluent disposal, are you not?

Dr. KULP. Right.

Representative HOLIFIELD. But he gets other contamination from other sources besides that particular industrial effluent.

Dr. KULP. Yes, but I would like to leave that out for the moment, and just consider the industrial.

Representative HOLIFIELD. All right.

Dr. KULP. My point is this; that if there is no threshhold, then we are taking the same risk essentially, by entering the atomic era industrially. In fact, we will probably wind up taking more risk than at least with present testing.

I would like to try to make this very clear, because I feel that in discussions I have read this point has not been made very strongly. The point is: If our maximum permissible concentration is significant here, namely, that 3 is small compared to 100, then 3 is also small compared to 100 in industrial applications. And if we are going to say that the maximum permissible concentration must be zero, then we cannot have any reactors, and we cannot have a nuclear era. Obviously, we are going to have a nuclear era and therefore we are going, if there is no threshold, to have deaths in the world as a whole from peacetime application, regardless of whether it is testing or not.

Chairman DURHAM. Doctor, is not there a difference there because of the fact that most of it is confined in the reactors safely, and in the release of atomic weapons you released into the air?

Dr. KULP. It is only confined safely within these prescribed limits. But if we say the limits are not right, they should be zero instead of 100, then we are no safer there than we are with anything else.

Mr. RAMEY. You do not have a strontium 90 problem, do you, from reactors as such, into the atmosphere, except in the event of an accident, and then that would just be a local problem, would it not?

Dr. KULP. We cannot go into the individual types of applications, but in any application that involves mixed fission products you have to get rid of radioactive wastes. And normally you get rid of high-level things, but then you have very low-level wastes which you can just throw away because it is below the MPC.

Representative HOLIFIELD. But your figures there are based on rules and regulations set up for the protection of the people, are they not?

Dr. KULP. Right.

Representative HOLIFIELD. But any violation of those rules would upset your calculation. I speak particularly of the sabotage of a

power reactor or the meltdown of a reactor such as has occurred in the experimental models. Now we are building these reactors of 100,000 to 260,000 potential kilowatt capacity. Assuming there was a sabotage, or assuming that one of these reactors would get out of control, then this would upset your whole calculation as far as the area contaminated from that particular reactor, would it not?

Dr. KULP. Yes. But the point I was trying to make was the contamination you would get from perfectly normal operations under all the present rules.

Representative HOLIFIELD. That is true. That is true. But accidents do occur, as you know. So while it is very comforting to be told that the rules are good, the speed limit has been set on the highways, but we know that people do exceed the speed limit and there are wrecks as a result.

Dr. KULP. And people get killed below the speed limit.

Representative HOLIFIELD. Those who go beyond the rules and regulations.

So that is a factor which we must also take into consideration as responsible Members of the United States Congress; is it not?

Dr. KULP. Yes.

Representative VAN ZANDT. Mr. Chairman?

Representative HOLIFIELD. Mr. Van Zandt.

Representative VAN ZANDT. Dr. Kulp, yesterday we were told that an all-out attack on the United States would require about 2,500 megatons of TNT equivalent, and it would destroy about 82 million people—50 percent by radiation, and 50 percent by blast and heat.

At the present time we have 2,500 megatons equivalent to TNT as far as radiation is concerned in the air. Based on your figure of 3 percent of the maximum permissible concentration, what would the figure look like after this 2,500 megatons of equivalent TNT had been deposited in the atmosphere?

Dr. KULP. Well, the difficulty here is the defining of the geographical area, but it would probably be more than a hundred times this.

Representative VAN ZANDT. A hundred times, with the possibility of a hundred times more?

Dr. KULP. This is not worldwide. Assuming a restricted area in the United States.

Representative VAN ZANDT. The Western Hemisphere.

Dr. KULP. Adjacent to where the detonation is concerned.

Representative VAN ZANDT. A hundred times more would be in the atmosphere. What would that do to those who would be left after such an attack?

Dr. KULP. Again I would refer you to the biological experts next week. It would appear on the present rules, if you got a hundred more times higher than this worldwide, this would have serious effects.

Representative VAN ZANDT. In other words, in addition to the 82 million people who were killed, and those that were suffering from radiation and heat, and so forth, who were not killed, the remainder of the population in the Western Hemsphere would be faced with possible death through this concentration of radiation that you speak of?

Dr. KULP. A certain fraction; yes.

Representative VAN ZANDT. Dr. Kulp, is it not true that you have the fact that, in addition to the reduction caused by the yield of the weapon, those who survive are also faced with this threat?

Dr. KULP. Yes.

Representative HOLIFIELD. Thank you very much, Dr. Kulp, for your presentation.

Dr. William F. Neuman, of the University of Rochester School of Medicine and Dentistry, will be the first witness this afternoon.

Before we recess I would like to insert in the record an article from Science magazine by Dr. Kulp, Walter R. Eckelmann, and Arthur R. Schulert entitled "Strontium 90 in Man," to gether with two letters to the editor of Science magazine. Also an article from the same publication entitled "Strontium Content of Human Bones," by Dr. Kulp and K. K. Turekian.

[Reprinted from Science, February 8, 1957, vol. 125, No. 3241, pp. 219–225]

STRONTIUM 90 IN MAN

J. Laurence Kulp, Walter R. Eckelmann, Arthur R. Schulert [1]

Radioactive fallout at great distances from atomic explosions produces both internal and external hazards to the human race. The external hazards result from the interaction of gamma rays in the environment on the genes of individuals, which produces an increased mutation rate. The increase in normal gamma background owing to fallout is very small, so far, and it is being carefully monitored (1). The tolerable level of external gamma radiation for genetic effects is not well defined (2). The internal hazard is primarily the development of bone cancer, because of the presence of strontium 90 (half-life 28 years). Libby (3) has discussed the general problem of strontium 90 in fallout and has presented considerable data (4, 5) on the concentration of this isotope in various parts of the chain from the atmosphere to man.

This article (6) summarizes the results obtained at Lamont Geological Observatory on the strontium 90 content in man (based on a worldwide sampling network) and attempts to evaluate the potential hazard. The work presented here is a part of a more comprehensive study of the geochemistry and biochemistry of strontium 90 that has been in existence at Lamont for several years (7, 8). The first experimental verification of measurable quantities of strontium 90 in animal bone, milk products, and soil was made at Lamont in August 1953 following the prediction by Libby, Eisenbud, and others in July 1953 (9) that it might be found in detectable quantities if low level techniques were employed.

At the present time strontium 90 can be found in all human beings, regardless of age or geographic location, provided that a sample of adequate size is available. As is shown here, these quantities are small compared with the maximum permissible concentration (MPC) (1.0 millimicrocuries of strontium 90 per gram of calcium) established by the National Committee on Radiation protection (10). However, the existence of measurable quantities makes it possible to analyze the present distribution of strontium 90 with regard to age, sex, diet, geography, and time. Such information is fundamental for making predictions about the probable effects of future nuclear explosions.

DISPERSAL

The route of strontium 90 from the time of fission to its uptake in human bones is known in broad outline. The explosion releases the strontium 90 into the air, where it is then carried for great distances. Eventually it is transported to the soil and becomes a part of the base-exchangeable alkaline-earth-metal ions in the upper few inches. Since plants take up this radioactive strontium along with their necessary calcium, human beings ingest strontium 90 from vegetables and milk products.

Kiloton explosions produce debris mainly in the lower atmospheres (troposphere), from which the strontium 90 is deposited in a few weeks (5). This

[1] The authors are on the staff of Lamont Geological Observatory, Columbia University, Palisades, N. Y.

debris is deposited in a restricted latitude. Thus the Nevada test series distributed strontium 90 largely over a narrow latitude band in the Northern Hemisphere, with a higher concentration in the United States than elsewhere. Megaton weapons, on the other hand, appear to put most of their strontium 90 into the stratosphere, where it is more or less uniformly distributed with respect to latitude. It then passes very slowly (about 10 percent per year) back into the troposphere (4), from which it is rapidly washed out. Megaton explosions, therefore, tend to equalize the worldwide fallout pattern. The local distribution will be modified by rainfall, vegetation cover, and topography, but the latest total fallout data (1) support a rather homogeneous distribution that shows maximum variations of only a factor of 3 at the longitudes of Africa and New York. The distribution in the Northern Hemisphere remains higher than that in the Southern Hemisphere, because of the kiloton shots from the Soviet and United States test sites.

It is now reasonably well established (5) that the scavenging action of rain is responsible for most of the deposition of tropospheric debris. Experiments made at this laboratory during the past 6 months confirm this conclusion. Other experiments at Chicago (11) and at Lamont (8) indicate that at least 60 to 70 percent of the strontium 90 which has fallen out in the United States is in the soluble form and is therefore available to plants. It is suspected that the megaton debris from the Pacific tests has a higher fraction of soluble strontium 90 than debris from other tests, but this remains to be confirmed. About 80 percent of the strontium 90 is found in the upper 2 inches of the soil, but in some cases detectable amounts may be carried down as far as 12 inches (8), because of the type of soil, topography, and drainage pattern. Measurements of the soil and plant content of strontium 90 per gram of available calcium in 1953 (4) can be interpreted as meaning that some plants have significant surface retention of strontium 90, or that the concentration of strontium 90 per gram of calcium in the 0- to 2-inch interval is not representative of the true environment of the roots. As the ground becomes progressively more contaminated with strontium 90, however, the surface effects become obscured. Thus, on the east coast of the United States during the Nevada tests in the spring of 1955, the surface fallout of strontium 90 was only a very small fraction of the total strontium 90 in the plants (8).

The total fallout of strontium 90 was estimated by Libby (5) at the end of 1955 to be about 13 millicuries per square mile in the upper midwestern region of the United States. The soil data of Hardy and Morse (4) suggest an average of about 15 millicuries per square mile for the United States. On the basis of the fallout of mixed fission products and an estimate of strontium 90 fractionation at long distances from test sites, Eisenbud and Harley (1) calculated a fallout of 13 millicuries per square mile for the United States in late 1955. By comparing the average total fallout on gummed paper for the United States in the fall of 1955 (1) with that for the world, a worldwide average deposition of strontium 90 on the soil of 8 millicuries per square mile can be calculated.

The amount of strontium 90 in the soil which gets taken up by the plant depends on the root depth, the calcium content of the soil, and the biological fractionation factor. Menzel (12) has shown that strontium is discriminated against by a factor of about 1.4 when it goes from soil to plant. The calcium content of the soil varies greatly. Values of 0.4 to 40 milliequivalents of exchangeable calcium per 100 grams of soil are common. Further, as noted in a foregoing paragraph, the concentration of strontium 90 drops rapidly with depth. These factors make it possible for the concentration of strontium 90 per gram of available calcium to vary by a factor of more than 100 for a given amount of fallout. Since the biological hazard may be stated in terms of concentration of strontium 90 per gram of calcium, it is clear, then, that merely to consider average values of strontium 90 in soil is not sufficient. Thus, although the fallout of strontium 90 per square foot in the New York area in 1955 varied by a factor of 7 (144 to 1010), the range in micromicrocuries of strontium 90 per gram of available calcium exceeded a factor of 40 (6 to 250) (8).

BIOCHEMICAL CONSIDERATIONS

Most people in the United States obtain their calcium through milk products. Here, fortunately, there is a discrimination factor of 7 against strontium from the plant that the cow consumes to the milk produced, according to experiments by Cosmar (13).

Regardless of the dietary source (milk products, vegetation, meat, or water), strontium 90 will follow calcium in the body, but it is discriminated against in going from the intestines to the blood by a factor of 2 to 3 (14, 15). Studies on human beings who have been given intravenous tracer doses of strontium 85 and calcium 45 simultaneously show that strontium is also discriminated against in the process of bone deposition. This, together with the fact that the body preferentially excretes strontium, results in a progressive enrichment of the bone in the calcium isotope following a single administration of the two tracers, the experimentally determined factor being 2.0 at 1 month and gradually increasing (16). On constant dietary intake, it would appear that an equilibrium enrichment of about 3 would be obtained in going from blood to bone, so that the total discrimination against strontium in going from the food to bone is about 8

Appreciable local variations in strontium 85 content per gram of calcium occur in individual bones after a single dose. The "hot spots" that appear on autoradiographs are probably of less consequence in the case of strontium 90 than they are in the case of radium, because the dimension of these localizations is usually much less than the range of the beta particle that is emitted from the strontium isotope. Table 1 shows that real differences in strontium 85 content per gram of calcium exists among the various bones of a particular skeleton. Although the data shown are for an individual who died 39 days after administration, the ratios proved to be relatively uniform for 7 other cases ranging from 3 hours to 125 days.

From the unpublished data of Trotter on the weights of individual bones in the human skeleton and from information on the percentage of calcium in the bones per gram of calcium exists among the various bones of a particular skeleton. load of strontium 90 from any given bone. The bone most frequently obtained at autopsy is the rib. It may be noted from table 1 that the concentration of strontium 85 per gram of calcium in the rib is twice that of the average body. Other bones frequently received in the worldwide survey are femur and vertebrae, which contain 0.72 and 4.2 times the average strontium 85 concentration of the whole skeleton, respectively.

These are the primary concepts and data that must be used in interpreting the worldwide human assay.

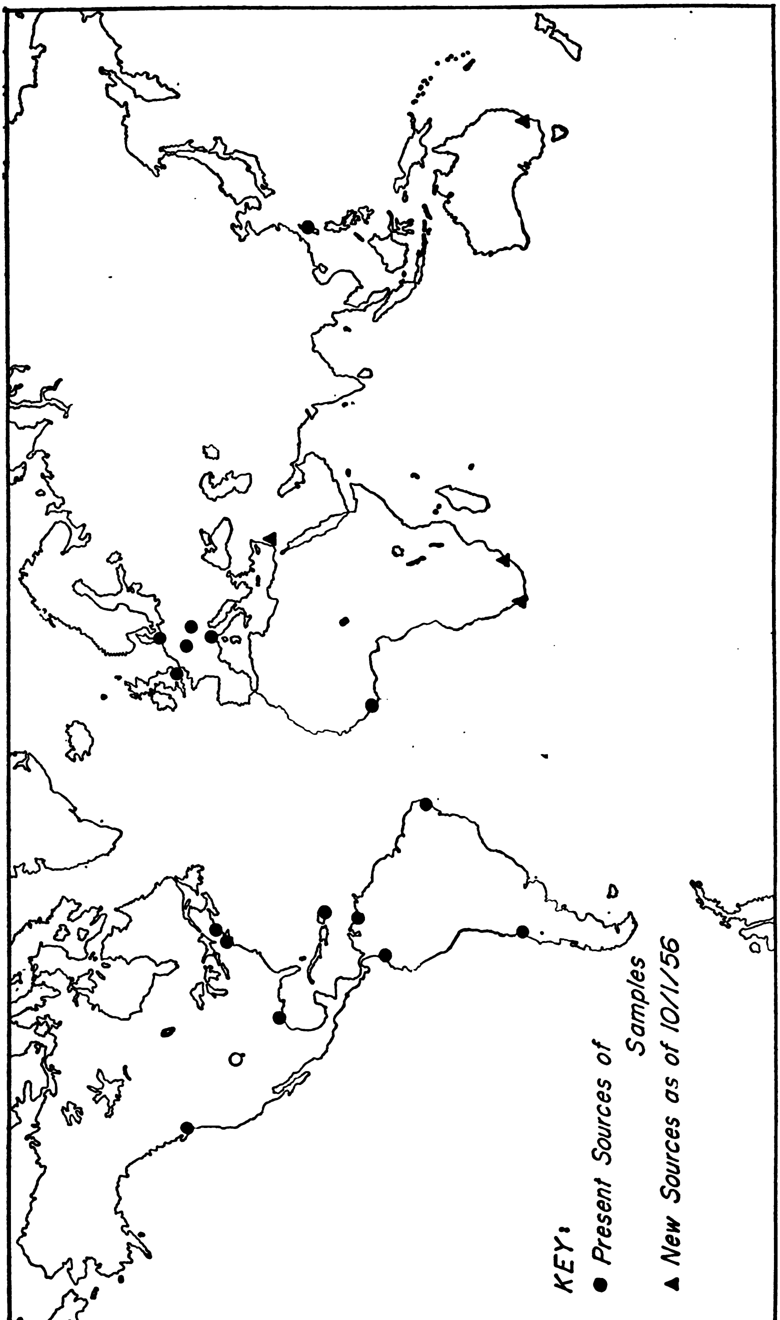

FIGURE 1. Worldwide network for collection of human bone samples. The triangles indicate new stations for which data are not yet available

TABLE 1.—*Relative size of bone and distribution of strontium 85 in human skeleton*

Bone	Percentage of skeleton (dry weight) [1]	Percentage of calcium of skeleton	Percentage of Sr-85 per gram of calcium [2]
Long bones [3]	52.5	57.9	0.0187
Femur	18.7	20.6	.0219
Humerus	6.9	7.6	.0171
Radius	2.3	2.5	.0170
Skull and mandible	17.9	19.7	[4] .0094
Rib	5.7	6.3	.0618
Vertebras	8.6	7.1	.128
Sternum	.3	.2	.138
Weighted average			.0303

[2] Data from Schulert, Laszlo et al., giving concentrations 39 days after administration of isotope. Other data taken from 3 hours to 125 days after administration of isotope show similar relative distribution of strontium 85.
[3] All the limb bones plus the pelvis. In averaging, it was assumed that the 3 analyzed are representative of the total.
[4] Skull.

SAMPLING

Autopsy samples of human bones were obtained from 17 stations in a worldwide network (17) (Fig. 1). To date, more than 1,500 samples have been received, and about 600 analyses have been made; the bulk of the samples have come from about 10 stations. The size of sample ranged from 1 to 200 grams of wet bone. An attempt was made to get as wide a geographic and dietary distribution as possible, but the distribution was necessarily limited by our contacts with physicians in certain centers. Future sampling will utilize a wider network, and considerable use will be made of integrated samples.

The bones employed were usually ribs, but those from Germany were femur shafts, and those from Switzerland, England, and Denmark were vertebras. In all cases the entire rib, shaft, or vertebras section was ashed and analyzed to avoid local variations that do appear both laterally and vertically in the bone.

The early results suggested that there was negligible strontium 90 in persons over 40 years of age; hence, sampling was concentrated in the younger age groups. It is clear that this is no longer true and that a broader spectrum is now desirable.

A few samples of adult bone measured at Lamont and many stillborns analyzed at Chicago (4) date as early as 1953, but for most localities the samples were procured in 1955, so that a clear definition of the rate of change of strontium 90 concentration cannot yet be made.

ANALYSIS

The radiochemical procedure (18) consists briefly of ashing the bone, dissolving in hydrochloric acid, precipitating calcium oxalate, igniting to calcium oxide, resolving in hydrochloric acid, adding nonradioactive yttrium carrier, and milking the yttrium 90 daughter of strontium 90 as the oxalate. Usually the first milking brings down some foreign activities so that a second one is required for the quantitative assay of yttrium 90. Purity is checked by monitoring the decay of the yttrium 90 precipitate. The yttrium oxalate precipitate is counted in a convenient low-level system that has been described elsewhere (19). This procedure makes it possible to determine less than 1 disintegration per minute of the strontium 90 sample. At the level of 10 disintegrations per minute, per sample, the precision is a few percent. Even at low levels of activity, the variation in the individual samples is considerably larger than the experimental error.

The data reported in this paper were obtained at the Lamont Observatory and at two commercial laboratories: Isotopes Inc., Westwood, N. J.; and Nuclear Science & Engineering Corp., Pittsburgh, Pa.

RESULTS

All of the analyses of strontium 90 in human bone reported in this study are summarized by locality in figure 2. The results are given in micromicrocuries of

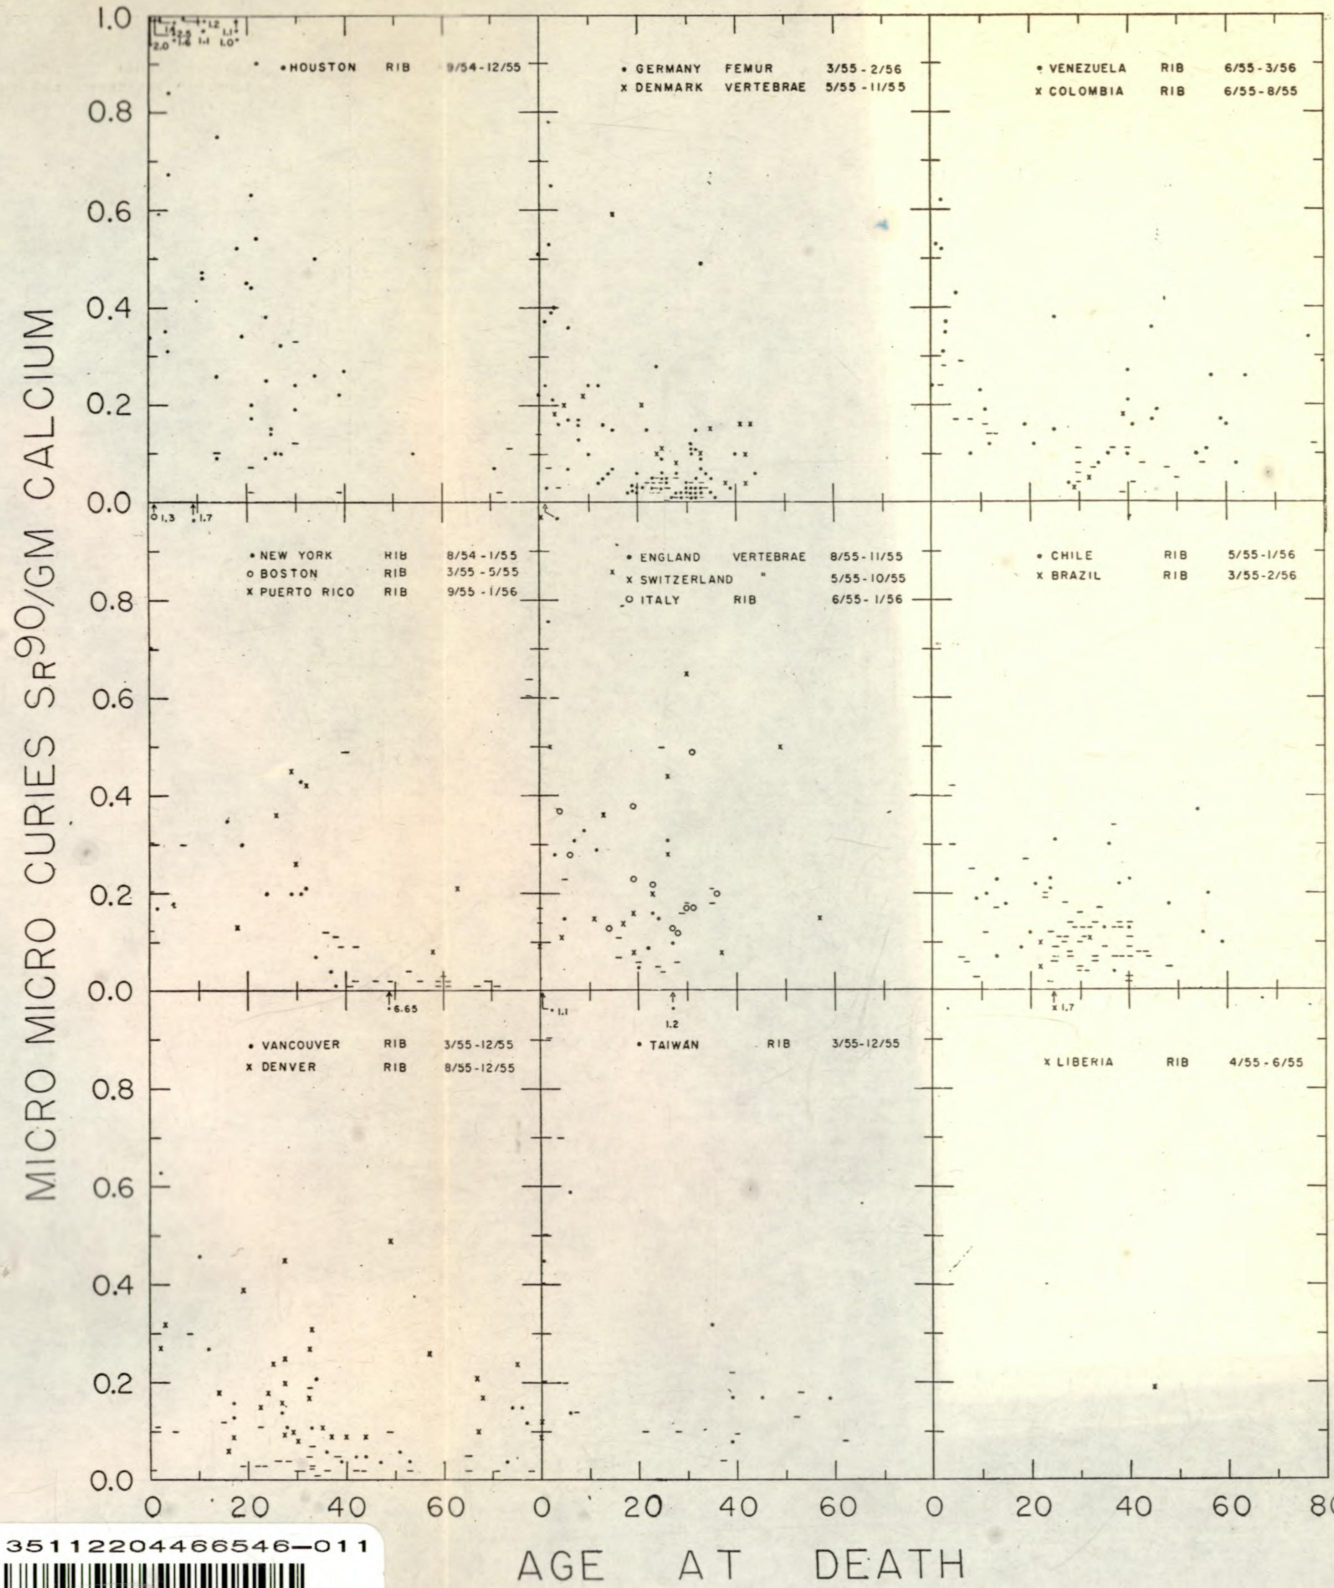

FIGURE 2. Strontium 90 content of human bone in 1955.

93299 O - 57 - pt. 1 (Face p. 699)

strontium 90 per gram of calcium. The dashes mean that the sample contained equal to, or less than, this amount. The error in a determination is generally less than 20 percent, but for a few of the very small samples or those with only a few hundredths of a micromicrocurie of strontium 90 per gram of calcium, it may be considerably higher.

Table 2 shows the averages for all localities broken down into age groups. All values in this table are normalized to an average skeleton, using the aforementioned factors. The weighted averages for each age group were calculated for each continent and for the world. Finally, a total maximum world average of the concentration of strontium 90 in the human skeleton was obtained. The average deviation for a given age group and locality was commonly around 50 percent. All samples whose analyses were reported as "equal to or less than X" have been assumed to contain X micromicrocuries of strontium 90 per gram of calcium for the purposes of this averaging. Thus table 2 actually represents the maximum average strontinum 90 content. For most localities, however, this makes little difference, because the numbr of such analyses was small or the analyses were in the range of low concentration. In the case of Chile and Brazil, however, the actual average concentration is probably about 25 percent lower than this maximum value.

One sample with very high concentration of strontium 90 was not included in the average. This sample was from Vancouver, British Columbia (49 years; tibia), and it had a concentration of 6.6±0.3 micromicrocuries of strontium 90 per gram of calcium. This would give a skeletal average of about 9.1 micromicrocuries of strontium 90 per gram of calcium. Analytic error owing to contamination appears unlikely, since other samples that were processed at the same time showed very low activity.

DISCUSSION

From the analytic data shown in figure 2 and table 2, the following tentative conclusions may be drawn:

(1) The present worldwide average content of strontium 90 in man is about 0.12 micromicrocuries per gram of calcium, or one ten-thousandth of the presently accepted maximum permissible concentration.

(2) The averages for the different continents are surprisingly similar, indicating that already the stratospheric drip of strontium 90 from megaton explosions is swamping the local concentrations from both the Nevada and the Soviet test sites. There is evidence, however, that Chile and Brazil have clearly lower concentrations than those localities in the Northern Hemisphere for which a large number of samples are available. The close similarity between Houston, Tex., and Bonn, Germany, for which good sampling is available, emphasizes that the differences as a function of longitude in the Northern Hemisphere are small. Since Taiwan has appreciable fallout from Pacific and Soviet tests (1), it is not surprising that its values are similar to those for North America.

(3) There is clearly an age effect, at least in the first 20 years. Young children have 3 or 4 times more strontium 90 per gram of calcium, on the average, than adults. This effect reflects the larger proportion of active bone in children.

(4) As was expected, the average strontium 90 content of human bone does not vary from one locality to another more than the average concentration of mixed fission products (1). For identical periods of time there is a fair correlation between these 2 factors for the 17 localities that were sampled for human bone.

(5) By averaging all samples from persons above 10 years of age, a large enough set is available for comparison between localities. In North America, for example, it is readily seen that the concentration in Vancouver is essentially the same as that in Houston, whereas the concentration in Denver is definitely lower (despite its proximity to Nevada). The New York average is not strictly comparable; it is low because samples from individuals 40 to 60 years of age comprised half of the total. These are the only ones in the table that were obtained in the spring and fall of 1954. At that time the strontium 90 content of adult bone was distinctly lower than it was in late 1955. (Note that the concentration in New York City milk had increased at least by a factor of 2 toward the end of 1955 from the level in 1954 (4).

(6) There are large deviations from the mean in the strontium 90 content in individuals of a given locality. The average deviation for most 10-year-age sets is about 50 percent. Figure 3, a log normal plot of the North American samples, illustrates that some individuals may have at least 10 times the average concentration. This is most probably related to diet.

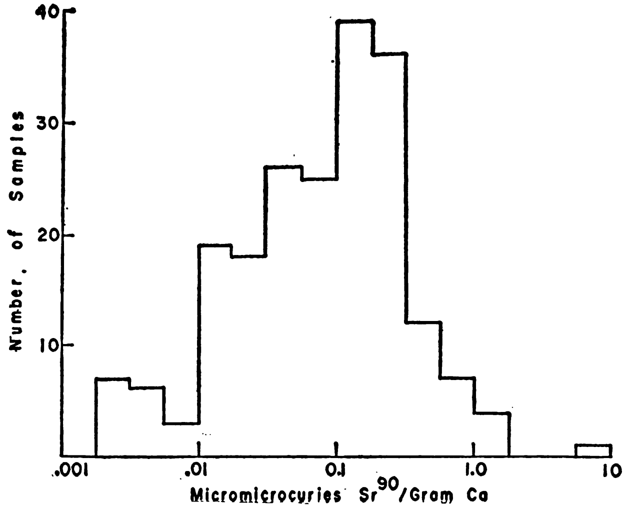

FIGURE 3. Distribution Pattern of Strontium 90 in Human Bone in North America

An attempt was made to find the time dependence of the strontium 90 contamination in human bone. The major difficulty is the limited time interval over which samples have been taken (mainly 1955). The New York samples of the spring and summer of 1954 in the older adults (40 to 60 years) were definitely lower (the average was less than 0.01 micromicrocurie of strontium 90 per gram of calcium) than in areas of similar total fallout in 1955, for example, Puerto Rico and Denver (averages were 0.14 and 0.08 micromicrocurie of strontium 90 per gram of calcium, respectively). Here an increment of 0.1 micromicrocurie of strontium 90 per gram of calcium, per year is evident. It now appears that stillborns may have a higher concentration than the average of the mother skeleton, at least during this early period of nonequilibrium. The Chicago data (4) suggests a 1953 stillborn average of about 0.12 micromicrocurie of strontium 90 per gram of calcium; this climbed to 0.17 by the spring of 1954. Six samples from Chile gave about 0.35 in mid-1955. The values for the comparable mother skeletons would have been 0.03 micromicrocurie per gram in Chicago in 1954 and 0.07 micromicrocurie per gram in Chile in 1955.

The samples from Germany were of sufficient size and number to make possible a significant comparision between the periods March to September 1955 and October 1955 to January 1956. The biggest difference was observed in the youngest age group, whose members would be the most sensitive to change in the strontium 90 concentration of the diet, because of their rapid growth. for the 0 to 9 age group, the averages were 0.21 and 0.34 micromicrocurie of strontium 90 per gram of calcium for March to September 1955 and for October 1955 to January 1956, respectively. A major increment in the known bone data should be observed in the present winter 1956–57 collection.

TABLE 2.—*Average strontium 90 content in man, 1955. (All values in micromicrocuries of strontium 90 per gram of calcium, normalized to the average whole skeleton. The numbers in parentheses give the total number of samples in the category.) The world average for all ages and locations is 0.12 micromicrocuries per gram of calcium; the average, including 1 sample of high value, is 0.14; and the world average for all samples assuming "equal to or less than" value are zero is 0.10*

The average American obtains about 80 percent of his calcium from dairy products and the remainder mainly from vegetation (20). In 1955 the strontium 90 concentration in milk in the United States was about 3.5 micromicrocuries per gram of calcium (4, 5). During the same period, field vegetation averaged about 20 micrimicrocuries per gram of calcium (5, 8) so that the average human population in the United States probably had a diet of about 7 micromi-

crocuries of strontium 90 per gram of calcium. Using the discrimination factor of 8 between diet and human bones, an equilibrium concentration of about 0.9 mircromicrocuries of strontium 90 per gram of calcium would be predicted for the average American. The actual concentration in 1955 was probably about 0.3 for young children and 0.1 for adults. These lower values reflect the time required for bones to equilibrate with the strontium 90 calcium ratio in the diet.

An estimate of the worldwide burden can be made by assuming that the average total strontium 90 fallout was 8 millicuries per square mile in 1955, and that the average amount of exchangeable calcium is 75 grams per cubic foot (4). Thus, if half of the fallout is in the upper 1 inch of soil, which contains 6 grams of calcium per square foot, an average concentration of about 25 micromicrocuries of strontium 90 per gram of calcium would be available to grains and grasses. Using a soil/plant fractionation of 1.4 and plant/milk fractionation of 7, the average worldwide concentration of strontium 90 in milk would be about 25 micromicrocuries per gram of calcium, and in vegetation about 18 micromicrocuries per gram of calcium. Assuming that 80 percent of the worldwide dietary calcium comes from milk products—as is true for the average American diet (20)—the predicted concentration of strontium 90 in the diet would be about 5 micromicrocuries per gram of calcium. This in turn would yield a predicted value of 0.6 micromicrocuries per gram of calcium for the average man when equilibrated with the fallout that existed at the end of 1955. The major uncertainties in the calculation are the source of calcium in the average world diet, the average calcium content of the soil, root depth, and possible direct foliar uptake.

In terms of hazard to man, there are two problems to be considered: (i) the average value for the world population and (ii) possible maximal concentrations. Locations near atomic test sites are not included in these considerations.

With regard to the strontium 90 burden of the population of the world in the fall of 1955, it can now be said that this is reasonably well known (0.12 micromicrocurie per gram of calcium) and that this burden is very small compared with the maximum permissible concentration (one-ten-thousandths).

The matter of predicting the maximum average human burden that will ultimately be occasioned from atomic explosions through the fall of 1956 involves several factors. The average burden will be determined by the average strontium 90/calcium ratio in the diet at equilibrium. Thus, if the fall 1955 concentrations in the diet were maintained, the average human being at all ages would reach a maximum of about 0.6 micromicrocurie of strontium 90 per gram of calcium. This would be the result of a worldwide fallout of about 8 millicuries per square mile by the end of 1955 (1). From the end of 1955 to the fall of 1956, another 2 millicuries per square mile would appear worldwide from stratospheric fallout. An additional 8 millicuries per square mile has fallen out since 1955 from high-yield weapons that have deposited all of their debris in the Northern Hemisphere (5). Libby (5) states: "In fact, we estimate at the present time that the total stratospheric reservoir, counting all sources, is about the same as it was 2 years ago—that is, 12 millicuries of strontium 90 per square mile, or the equivalent of 24 megatons of fission products calculated as a uniform worldwide distribution." Taking decay into account, a total quantity of 26 millicuries per square mile would be available in the United States for equilibration with the human skeleton by 1970. Thus, from explosions that have already occurred, the average human bone in the United States should contain about 2 micromicrocuries of strontium 90 per gram of calcium by 1970, whereas the worldwide average concentration should be about 1.3. This will have been the result of about 50 megatons of fission. On this basis, 35,000 megatons of fission would be required to bring the average concentration in the world's population up to the maximum permissible concentration.

The most important problem lies with individual variation. By direct experiment, it has been found that the distribution curve is quite sharp (fig. 3 and table 2). Although food grown in restricted areas of low available calcium content could have 10 to 100 times the mean, it is clear that the general mixing of food sources in the diet of an urban population would make it impossible for most people of the world to exceed the average concentration of strontium 90 by more than a factor of 10.

The theoretical estimation of the maximum concentration of strontium 90 that some individual or a small group of individuals might receive at long distances from atomic test sites is a complex problem involving a number of parameters that are at present subject to large uncertainties. The highest concentrations will be found in isolated individuals who obtain their total food supply from a restricted area that has very low available calcium in the soil (21).

SUMMARY

The worldwide average strontium 90 content of man was about 0.12 micromicrocurie per gram of calcium (one ten-thousandths of the maximum permissible concentration) in the fall of 1955. A few values as high as 10 times the average have been obtained.

The value is in accord with the predicted value based on fallout measurements and fractionation through the soil-plant-milk-human chain.

With the present burden of strontium 90, this average level should rise to 1 to 2 micromicrocuries of strontium 90 per gram of calcium by 1970.

12. R. Menzel, personal communication. Early experiments had suggested a discrimination factor as high as 2.8 for the Sr/Ca fractionation ratio in going from soil to plant. This was used by Libby for computation (5). It now seems likely that the correct value is close to 1.4 for several reasons. (i) The early experiments involved some uncertainty either in the quantity of tracer or the degree of equilibration. (ii) New experiments by Menzel on four widely different soil types using both radioactive and common isotopes gave a factor of 1.4. (iii) The majority of the Sr-90 has now been in the soil for long periods compared with the laboratory experiments; hence near equilibration appears probable. (iv) Other workers have recently reported experiments that gave about 1.4 [K. Larsen, UCLA Rept. No. 380 (6 Nov. 1956); H. I. Bowen and J. A. Diamond, J. Exptl. Botany 7, 264 (1956)].

Strontium 90 in Man

The strontium 90 data on the detention of fission fallout in man, as reported by J. L. Kulp, W. R. Eckleman, and A. R. Schulert (Science 125, 219 (1957)), provide the first sound basis for evaluating the biological hazards from Sr–90 on a quantitative scale. While the authors present excellent data, their conclusions are open to serious criticisms, a number of which are itemized in the following paragraphs.

(1) The biological hazard of Sr–90 is most important in human beings born since the Castle series of nuclear tests (beginning with the March 1, 1954, explosion). Thus the pertinent age group, for measurements made in 1955, is 0 to 1.5 years. It is somewhat misleading to present Sr–90 bone retention data as an average value for ages 10 to 80. This is especially significant since infants show a much higher uptake of strontium than do adults.

(2) Statistics on Sr–90 retention in infants are too limited to permit careful evaluation of the biological hazard. Futhermore, it is again misleading to speak of averages for strontium retention in infants. Our concern should be with the fraction of infants who get, say, 10 times the average value, for we certainly do not wish to consider the radiation risk on a total basis.

(3) The authors assume that their data reflect the establishment of an equilibrium condition in fallout and uptake of Sr–90. About a year elapsed between stratospheric injection of the fission debris and the time of bone measurement. The bomb-to-bone sequence is an intricate one involving the possibility of hold-up in the food chains. For example, dairy cattle fed on stored herbage would contribute less Sr–90 to dairy products than those on open range.

(4) In the case of stillbirths, Sr–90 data may be distorted by nonnutritional calcium prescribed for many pregnant women.

(5) The authors continue the Atomic Energy Commission practice of reporting Sr–90 concentrations in terms of maximum permissible concentration (MPC) which are strictly meant to apply only to healthy, occupationally exposed adults. The MPC for children, to be consistent with the recommendations of the National Commission of Radiological Protection ought to be one-twentieth the occupational MPC.

(6) Values for MPC have been revised downward steadily during the past two decades as more knowledge of the ultimate biological effect of skeletally retained radioelements has accumulated. In view of the greater radiosensitivity of infants to nuclear radiation, the global exposure involved, and the lifetime irradiation periods, it may well be that the appropriate MPC for evaluating the global Sr–90 hazard should be one one-hundredth the occupational value. The MPC for Sr–90 is based on comparison to the radium MPC, which, in turn, hinges on our experience with radium poisoning in human beings. Practically no data are available for radium retention in children and, in addition, very few radium-retention studies on human beings have been carried out over a period of 40 or 50 years.

(7) In projecting their estimates of Sr–90 retention through 1970, the authors make no allowance for additional nuclear tests. In view of the fact that the British will test weapons in the megaton range within a few months and the Soviets may overcome their continental proving ground limitation so that a Castle series of tests may be undertaken shortly, it seems naive to assume a vacuum in testing from 1956 to 1970.

In addition to these seven points, one should consider the role of concentration factors in fallout, the selectivity of global fallout, the possibility of different fallout patterns for bomb debris injected into the stratosphere at points other than the United States and U. S. S. R. test sites as well as the influence of different substrata on fallout phenomenology. Nor should one neglect the possibility of ecological upset owing to concentration of radioelements in nature.

Any meaningful evaluation of the Sr–90 hazard must seek to assess the risk of excessive radiation exposure to the most radio-sensitive groups of the total population. Because of the global nature of the fallout, the problem of risk-evaluation should be undertaken on an international basis. No governmental group within the United States should undertake to assume or calculate risks for peoples of foreign lands. The United Nations has established a committee to in-

vestigate the biological effects of nuclear fallout, and it is to be hoped that technical reports will be forthcoming soon. Then attention may be focused on weighing the probable risks of future bomb tests, and it may be possible to fix a limit to the annual testing of nuclear weapons to keep stratospheric pollution within safe limits.

It is salutary that the Atomic Energy Commission has sponsored such high-quality scientific research and even more hopeful that phases of this work are emerging from the classified category. Independent analyses of the problem, such as those appearing in the Bulletin of the Atomic Scientists, now rest on a more solid foundation of fact that was heretofore possible.

RALPH E. LAPP,
Arlington Towers, Arlington, Va.

Although we share Ralph Lapp's concern for the seriousness of the Sr–90 problem for the world population, we wish to dissent from some of his interpretations of our data.

(1) We quite agree that momentarily the biological hazard is greatest for young children. We do not see how a discussion of the average concentration of Sr–90 is indults is misleading when we give all the individual data, as well as the averages of 10-year-age intervals, and definitely conclude that "children have 3 to 4 times more strontium 90 per gram of calcium * * * than adults."

(2) We did not conclude that the present data permit "careful evaluation of the biological hazard" in children. In fact, we made it clear that many more data are urgently needed. The important statistical quantities, of course, are the mean and the standard deviation.

(3) We clearly pointed out that the present situation does not represent equilibrium but that reasonable predictions can be made of what the equilibrium situation may be. By examining the steps in the bomb-to-bone chain, we were able to conclude that the quantity of Sr–90 in human bone is approximately that predicted from our knowledge of the total fallout and the fractionation factors in the chain. Actually, the time scale of importance is on the order of a year, and in this period the milk appears to be fairly well equilibrated with the soil. When milk is the major source of calcium in the diet of young children, the children will likewise approach a transient equilibrium.

(4) The data on stillborns did not involve the average predicted for ultimate equilibrium.

(5) We most emphatically did not present our data in maximum permissible concentrations for several reasons, not the least of which is the current debate among competent medical scientists on what this value should be. We reported all our data in absolute units of micromicrocuries of Sr–90 per gram of calcium. We discussed the data relative to the one official Sr–90 level existing at the time we wrote the article—that is, the maximum permissible concentration for industrial workers stated in the National Bureau of Standards Handbook No. 52.

(6) The setting of the maximum permissible concentration is not in our sphere of scientific competence. This was not one of our conclusions.

(7) We could have calculated the average concentration of Sr–90 in man in 1970 either by using the known number of atomic tests to date or by assuming some unknown arbitrary number. We chose the former and clearly stated our assumption. The point here was to show what will ultimately get into man from a known quantity of debris produced. It was not our intention to calculate how much might be present in man by 1970 assuming some grave political situation.

It is hoped that current experimental work in this laboratory and elsewhere will make it possible to provide information on some of the other problems which Lapp and others have raised. Although there will remain much area of debate, new data to be published shortly will place some further limits on the area of speculation. In reporting the laboratory data on this controversial and globally important subject, we have tried, and will continue to try, to present it as objectively as possible, so that the scientist-citizen such as Lapp may discuss the sociopolitical problem in as well informed a manner as possible.

STRONTIUM CONTENT OF HUMAN BONES

The refinements of analytic techniques for trace elements, together with a growing interest in the distribution of trace elements in human tissues, has resulted in a continued addition of information on these elements to the biochemical literature. The present paper (1) reports strontium analyses on 277 human bones from a worldwide sampling.

Hodges et al. (2), investigating the strontium content of human bones by an emission-spectrographic technique, found for a limited sampling an average of 220 parts per million for bone ash. Tipton (3) has found a lower value for bones (120 parts per million), also using an emission-spectrographic technique.

The present paper reports results indicating that there are marked regional differences. It is possible that the aforementioned discrepancy may be explained on this basis. It is also possible that regional effects may be confounded with systematic errors in the analytic data. The investigation reported here is an attempt to resolve these uncertainties and to explore the significance of the data as related to biochemistry and geochemistry.

The bone samples were analyzed (4) as ashes that had been prepared at 800° C. for 12 to 24 hours. The individual bone samples were received from the contributors in various forms of preparation or in different stages of desiccation; hence, there can be no significance attached to the loss on ashing. It was felt that the most significant number that could be determined was the ratio of strontium to calcium, inasmuch as this would avoid any of the ambiguities of varying histories of preparation or variations owning to density of bone mineral.

For values above 0.35 (percent Sr/percent Ca times 10^3) the coefficient of variation is about 9. The specimens were run in duplicate, giving a standard error of ± 6.5 percent. On the 95-percent confidence level, this means an error of ± 13 percent for values of 0.35 (percent Sr/percent Ca times 10^3) and higher. Values below 0.35 (percent Sr/percent Ca times 10^3) have a higher error.

The study reported here (5) indicates agreement with Hodges, et al, (2), in that no effect of bone type on the ratio of strontium to calcium was observed. In addition, there is no correlation with age or sex. The main source of variation appears to be related to regional influences, because, as table 1 indicates, there are marked differences in the means of several geographic areas. From table 1 it can also be seen that the standard deviation varies for different regional samples. Where large variances occur, they may either be attributed to a more mobile population or to regions with diverse geologic, and consequently geochemical, environments. In some areas the ethnic diet may play an important role.

TABLE 1.—*Summary of data on regional variations in the strontium of human bones*

Region	Number of specimens	Average (percent Sr/percent Ca) $\times 10^3$	Standard deviation	Range
Colorado	28	0.61	0.27	0.34-1.35
Texas	12	.54	.16	.25- .80
England	3	.67	.55	.30-1.50
Switzerland	7	.35	.15	.11- .55
Cologne	21	.36	.11	.21- .68
Bonn	15	.35	.12	.17- .52
Denmark	2	.89	.23	.73-1.05
Italy	9	.71	.14	.49- .88

Puerto Rico	5	.62	.30	.37-1.05
Vancouver	21	.50	.15	.33- .75
China	19	.67	.16	.42-1.00
Japan	5	.70	.14	.58- .93
India	29	.69	.28	.34-1.50
Liberia	1	1.25		

It has been established by Turekian and Kulp (6) that there are marked regional differences in the strontium content of almost all types of rocks composing the geologic realm. Waters draining from these rocks and plants growing in these areas would taken on the strontium complexion of the locale. This has been demonstrated for a large number of elements and is a useful tool of geochemical prospecting. These regional differences are the most likely reasons for the variations in the strontium content of human bones from one area to the next.

It may be possible to check this conclusion by examining human bone tissue from a known high Sr/Ca area. The Waukesha (Wisconsin) water supply (7) has been found to have 30 to 50 ppm strontium and 50 to 90 ppm calcium. Hence, the region should have a very high Sr/Ca ratio. It would be interesting to check bones from such a locale.

A histogram of the strontium content of the 277 human bone specimens analyzed (fig. 1) approximates a normal distribution. If the 277 observations can be considered a large enough sampling of the world, then it is possible to arrive at an average ratio of strontium to calcium in human bones. This average is 0.60 (percent Sr/percent $Ca \times 10^3$). If it is converted to parts per million strontium on the assumption of pure calcium phosphate ash, this value is equivalent to 234 ppm. This compares closely with the value of Hodges et al. (2), but, considering the marked regional variations, it may only be fortuitous.

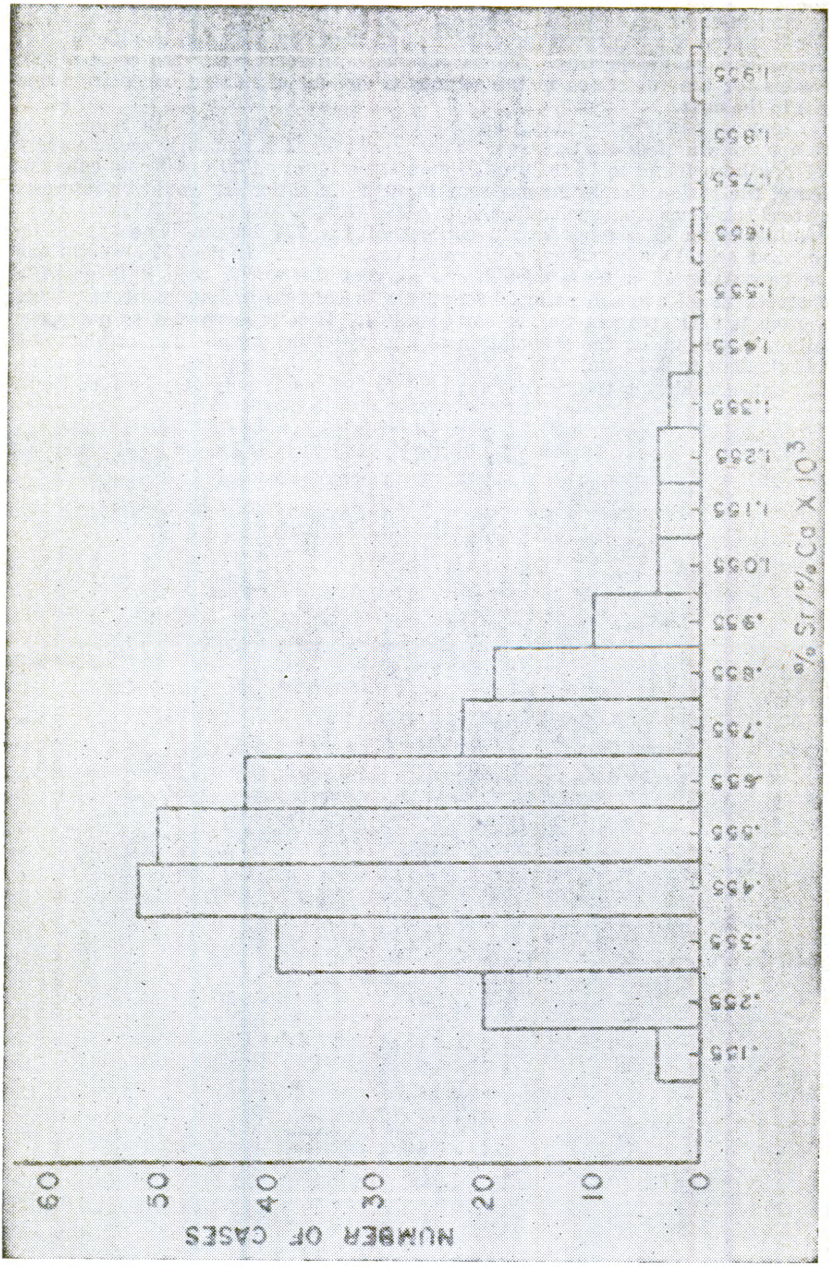

FIGURE 1. Histogram of Sr/Ca ratios for 277 human bone specimens.

Turekian and Kulp (6) have demonstrated that the average (percent Sr/percent Ca$\times 10^3$) ratio in igneous rocks ranges from 6.5 to 23 and in sedimentary rocks from 1.5 to 6; hence, it is evident that the human body markedly discriminates against strontium relative to calcium when compared to the natural environment. This has been documented by Alexander et al. (8) in the case of several small laboratory animal specimens. The mineral apatite occurring in nature, which compares in part to some portions of the skeleton, is reported by Noll (9) to have from 0.1 to 4.5 (percent Sr/percent Ca$\times 10^3$). Hence, the vital effect of the organism is seen operative in the differentiation of strontium and calcium in human bones. Schulert (10) of the Lamont Observatory has demonstrated the existence of such differentiations using Sr–85 and Ca–45.

It is conceivable, considering the foregoing information, that human bones that have started in the direction of fossilization should possibly show a time-dependent increase in the strontium content upon burial. Hence, it is possible that this may be used in a manner similar to the fluorine method for relative chronologies. This aspect of the study awaits further exploration.

4. Strontium-free calcium phosphate was prepared by ion-exchange separation. Standards for the spectrographic analyses were then made by mixing this strontium-free calcium phosphate and calcium phosphate with a known strontium content. All measurements were made using the Jarrell-Ash Ebert grating spectrograph and the Jarrell-Ash 2100 microphotometer. The critical constants are as follows: approximately 5 mg of bone ash was weighed into necked deep crated 3/16-in. electrodes (National Carbon Co. No. 4000) and arced at 16.5 amp to completion. A glass filter, to absorb second-order interference lines, was placed before the 30μ slit. A rotating sector allowed the transmission of 35 percent of the light. Kodak SA No. 1 film was used and D–19 developer at 3 min and 20° C. The Sr 4607 line was used as the analysis line and Ca 4579 was the monitor line.

Representative HOLIFIELD. The committee will stand in recess until 2 o'clock.

(Whereupon, at 12:20 p. m., the committee recessed, to reconvene at 2 p. m., of the same day.)

AFTERNOON SESSION

Senator ANDERSON. The committee will be in order. The first witness this afternoon will be Dr. William F. Neuman, of the University of Rochester School of Medicine and Dentistry. I am happy you are here today, Dr. Neuman.

STATEMENT OF DR. WILLIAM F. NEUMAN, SCHOOL OF MEDICINE AND DENTISTRY, UNIVERSITY OF ROCHESTER [1]

Dr. NEUMAN. It was my impression that I was to discuss discrimination factors in the human food chain. Attesting to the importance of these discrimination factors, many previous witnesses have found it necessary to discuss them and to use them in their calculations. Because of this previous discussion, and because the hearings are falling behind schedule, I shall be very brief.

I would like to show that the discrimination factors are very important and permit us to relate human bone levels of Sr–90 to the rate of weapons testing.

Let me, at the outset, underscore the remarks of Dr. Kulp to the effect that there is agreement in the scientific community. We are all agreed that present levels of Sr–90 in human bone are quite low and that the associated hazards are quite negligible. It is predicting the future that we, as scientists, part company.

Let me also stress that the survey data given by Drs. Kulp and Eisenbud, though extremely important and valuable, are of limited use in making predictions. These data are inextricably bound to past conditions: testing rates, types of weapons exploded, and so forth. Furthermore, to extrapolate from these data, one must make some guess, some assumption, regarding the fraction of the final equilibrium that human bone has currently achieved. This assumption is quite uncertain.

For purpose of predicting, I submit that the most reliable data from which to extrapolate are those related to the natural strontium in our biosphere. After all, we have been at equilibrium with natural strontium for many generations. Dr. Kulp and Eisenbud have had occasion to refer to these data themselves.

The beauty of using natural strontium as our model is this: Only two assumptions are necessary, first, that strontium 90 behaves like natural strontium (which is not an assumption at all) and, second, that strontium 90 formed in nuclear explosions will show complete mixing with natural strontium and follow the same distribution pattern. One might question this assumption. It is somewhat optimistic, tending to minimize the final evaluation of potential hazards.

The subject of discrimination factors is based on a classic principle enunciated by the famed French physiologist, Claude Bernard—the internal milieu. The basic idea was this: Life originated in the sea. As new evolutionary forms appeared, they were at a disadvantage if they found the composition of the sea not to their liking. They died out. By the time there evolved larger forms, which could leave the sea, these animals could not divorce themselves from their chemical heritage. Their body cells required a fluid environment very much like that of the mother fluid, that ancient sea.

[1] Date and place of birth: 1919 in Petoskey, Mich. Education: Michigan State College, 1936; University of Rochester, Ph. D., 1944. Work history: Member of the staff of Rochester University since 1944; associate professor of pharmacology in 1950, associate professor of biochemistry in 1955. Associated with atomic-energy project at university (chief of biochemistry section). Eli Lilly award in biological chemistry in 1955. Radiological monitor at Bikini bomb tests; representative of AEC to visit European installations in 1952; scientific adviser to State Department at Geneva Conference on Atoms for Peace in 1955. Fields of interest: Bone chemistry and bone metabolism, matabolism of fission products, radiation effects. (Submitted by Witness.)

Within us, today, special cells, special organ systems are constantly at work maintaining the body fluids at this ideal composition, despite wide variations in intake resulting from whim or fortune.

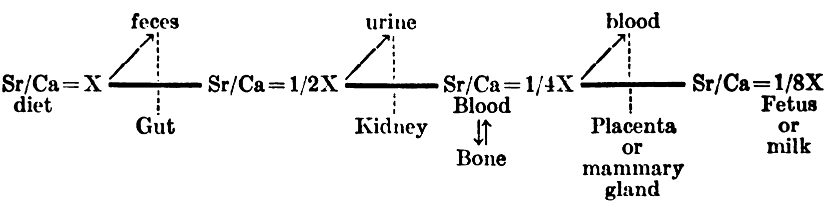
These special organs select and conserve those substances which are needed, eliminate those which are not needed or unwanted. However, these specific selective and regulatory processes are based on natural law, not on magic. They are not perfect. Just as dispensing machines can be made to operate with a slug having a shape, weight and properties similar to a genuine coin, so also can the body be "fooled" when presented with a chemical counterfeit.

Natural strontium is the chemical counterfeit of calcium, an alkaline earth which is required for the maintenance of health and well-being, as we have learned from television, a requirement which we never outgrow. Actually, natural strontium is an excellent counterfeit. It is so good, it can be considered legal tender in many body processes. Consequently, it is relatively nontoxic and harmless. Because of its widespread occurrence in soils and rocks, strontium is found in our drinking water, in our food, and, of course, in our bodies. Like calcium, about 99 percent of the strontium is found in bone.

No counterfeit is perfect, however, and there are slight differences in properties between strontium and calcium which permit our regulating systems to select calcium preferentially, or to discriminate against the less desirable strontium.

Where are the sites at which these discriminations occur? They occur in those organs which are charged with the responsibility of maintaining normal calcium levels in our internal milieu: the portal of entry, the gut; the exit, the kidney; and in two organs specially concerned with assisting the developing infant to maintain its internal milieu, the placenta and the mammary gland. As a crude but very useful approximation we can say that at each of these organs, calcium is preferred 2 to 1. Stated another way, the ratio Sr/Ca presented to the organ is reduced by half in passing the organ system.

Thus:



Given a certain strontium-calcium ratio in the diet—we will call it X—the strontium ratio on reaching the blood will become one-half X, in passing through the gut, with some strontium preferentially appearing in the feces. Upon reaching the blood, it passes the kidney and again we have a preferential reabsorption of calcium to the exclusion of some of the strontium. In this case, the strontium appears in the urine preferentially, which leaves a factor of approximately one-fourth X. The circulating fluids reach the bone areas. In the bone, we know of no real discrimination. Therefore, we can say, as a rough approximation, bone levels will be in strontium content about

one-quarter that of the diet. In the developing embryo, the placental barrier will reduce this further so that the lightly mineralized bone of the infant will be only about one-eighth of the Sr/Ca ratio of the mother's diet. Similarly, milk will exhibit a ratio only about one-eighth that of the diet. This is a crude illustration of how these processes interact within the animal.

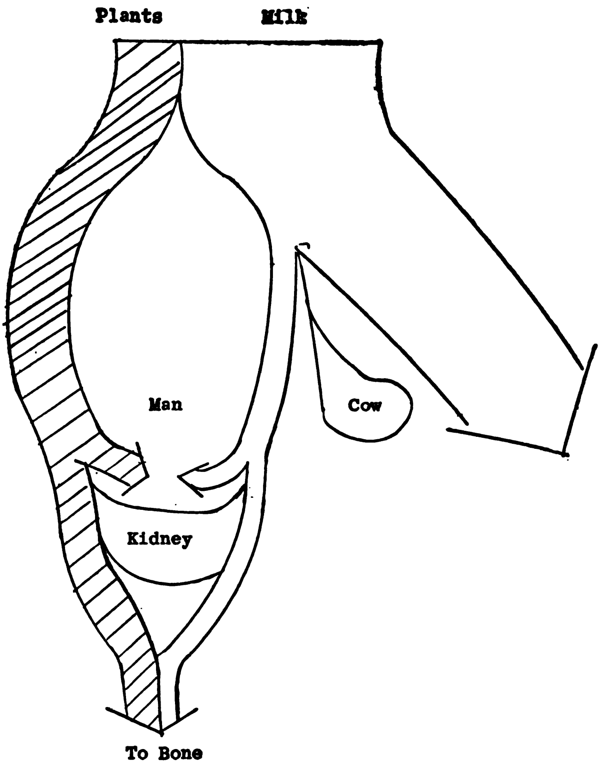
I should point out however, that the discrimination which occurs in the gut is subject to some influence. If the diet is primarily milk, as it is in this country, the discrimination by the gut seems to be much less. It is nearly wiped out. Therefore, we find that, without this favorable discrimination, the person on a milk diet will put down a bone which exhibits a strontium to calcium ration about one-half that of the diet.

Now I would like to go over again something that was discussed by Dr. Kulp this morning. In traveling from plants to human bone we have, really, two alternative paths. One, in which the calcium from the plants goes through the cow and is subjected to the favorable discrimination factors of the cow; one, in which calcium of the plants reaches the diet directly without passing through favorable discrimination factors. Doctor Kulp stressed the fact that most of the calcium comes through the milk chain. This is true, but if we use the discrimination factors best known today, we find that, in terms of strontium, most of the strontium may come through the plant side of the food chain. The reason for this is the favorable discrimination against strontium in the milk chain.

I will try to illustrate this with a drawing but because of my limited art talent, this may be less clear than what I have already said.

We can take a band as coming from plants as being about one-fourth the total strontium-calcium supply and a band three times as wide from the milk side. If we pass through the cow seven-eighths of the

Overall Chain



The Origin of Bone Strontium.

strontium will be discriminated against, and only one-eighth of the strontium then, will reach the human.

Although we start with only one-fourth of the strontium from the plant side, all of this reaches the human with no discrimination along the way. In terms of dietary supply of strontium, more is coming from the plant side than from the milk chain. If we then put in the favorable discrimination of about one-half to one-fourth for the human, we find that the overall ratio in bone is reduced to about one-sixth to one-eighth of the plant levels on the basis of our crude example.

I say the value one-sixth. That is very rough. It is based on the crude approximations made in our original model. What is the proper number to use? How reliable is it? And finally, what does it mean? I think at the present time the best figure to use is one-eighth. This number is a number proposed by Dr. John Lautit, representing the British point of view. It is the mean value of a discussion at which most of the experts in this country were present last April 23. At the present time, this value seems to me to be quite well established—certainly within a factor of 2. The overall discrimination I cannot believe would be less than one-fourth or greater than one-sixteenth.

This value is really quite good. It is based on four general types of experiments. The administration of labeled strontium to animals and to man to determine the metabolism pattern and distribution in the animal and so on. The second kind of experiment involved the simultaneous administration of radioactive strontium and radioactive calcium to animals and man for a direct comparison of these two elements. It has come also from the chronic lifetime feeding of animals of diets containing fixed ratios of radioactive strontium to normal calcium.

Finally, and most importantly, it comes also from the direct determination of natural strontium-calcium ratios in the bones of man and animals and their diets. I consider this area to be much more reliable than many other of the elements of indecision with which we will be faced next week.

Mr. RAMEY. Has this value been as refined all the way through or did you start out with a higher one and gradually work to this as a result of better measurements?

Dr. NEUMAN. If you are asking me personally, may I say that I have been very lucky. I have not had to change my numbers. My original estimates of what this number might be were rather tenuous because much of the data were not yet in. I find myself really very lucky in that the mean of my original estimates and that final agreed upon differ by only about 16 percent. Others were not quite so fortunate. We find that many made estimates originally that were quite favorable. I think now we are agreeing more and more that the factor 8 is probably the best figure to use. We may have to revise this. But I do not believe it will be revised more than by a factor of 2.

This value represents discrimination in the chain from plants to bone only. What about the possibility of discrimination in going from ground to plant? I am frankly quite uncertain and I am willing to stand corrected. From the data I have been able to find and study there seems to be no adequate basis on which to decide at present, and I recommend heartily that no effective discrimination be assumed but with the clear and important qualification that this assumption must be continuously scrutinized and changed as soon as new data permit.

I shall take, then the overall discrimination process from ground to human bone as totaling one-eighth.

Mr. RAMEY. Does that differ from Dr. Kulp's testimony this morning?

Dr. NEUMAN. Dr. Kulp used the same factor for milk that I did, but I believe he used an overall factor of 14 and used the milk side only. I am not sure.

Is Dr. Kulp here?

(No response.)

Dr. NEUMAN. I believe he used the factor of 14, which is going down the milk side, ignoring that which comes from the plants directly. That is a little optimistic in my opinion.

What is the importance of this number in our present considerations? It seems to me that this figure permits us to calculate very simply the rate at which fission products can be released by the various testing programs. Only two bits of information and one decision

are needed. We need to know the variation of the strontium to calcium ratio in human bone. We need to know the variation in the pattern of strontium 90 fallout and evaluate it and we thus, third, make a decision regarding the maximum permissible allowable, some kind of concentration to be permitted in human bone.

This morning Mr. Anderson asked a number of questions which would relate predictions of bone level to test rate. All of the calculations that were prepared in advance were on the basis that no more strontium 90 was being produced.

I would like to go quite the other way around and calculate the permissible production of fission products based on a given human bone level.

The assumption I would like to make is: When we have loaded our biosphere with the permissible amount of strontium 90, the amount of testing that can be done, the amount of strontium 90 that can be produced, will be equal to that which decays in any given year. This will maintain us at the steady, loaded level. This would amount to 2½ percent per year.

Therefore, if we calculate the maximal tolerable biosphere load we automatically have calculated the permissible production of strontium 90 in any given year.

This is such a simple equation that I am frankly embarrassed. These are supposed to be very difficult matters, but I find in the final analysis, that the calculation does not involve calculus but rather only arithmetic.

Thus:

2.5 percent tolerable ground levels = Annual test rate

$$\begin{matrix}\text{Toler.}\\ \text{gnd.}\\ \text{levels}\end{matrix} = \text{MPC}\cdot\begin{matrix}\text{Correction}\\ \text{for}\\ \text{variation}\\ \text{in}\\ \text{population}\end{matrix}\cdot\frac{1}{\begin{matrix}\text{Discrimination}\\ \text{factor}\end{matrix}}\cdot\begin{matrix}\text{Correction}\\ \text{stratospheric}\\ \text{holdup}\end{matrix}\cdot\begin{matrix}\text{Correction}\\ \text{for}\\ \text{nonuniform}\\ \text{fallout}\end{matrix}$$

where

$$\text{TGL} = \text{MPC}\times\frac{1}{V_1}\times 8\times 1.2\times\frac{1}{V_2}$$

We must, to begin, decide on what will be the maximum permissible concentration to be tolerated in the human bones of a large population. without reaching that decision, because this obviously will be discussed next week, I would like to continue with the calculation. We must correct this number by a variation. It is obvious that we can't have the general population averaging the maximum level. If we did this, half the population would be over the maximum. If we are deciding on a maximum level, then it is a maximum level and people should not exceed it. So the maximum permissible concentration must be revised downward by a number which evaluates the variability between individuals. I will discuss this in just a moment.

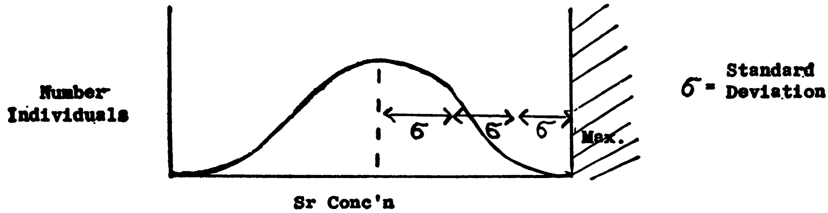
Now we find that we can tolerate more strontium 90 in our biosphere because of the favorable discrimination against it in food chain. We can, therefore, multiply by our overall average discrimination factor of 8.

We must consider the matter of stratospheric holdup. Obviously, if some of the strontium, in reaching the food chain, decays in its path through the stratosphere, this is all to the good and we can therefore

correct our value upward, depending on the amount of decay that occurs between the site of detonation and its entry into the food chain. I believe a factor of 1.2 is a reasonable number. This is because 20 percent of the strontium decays before it gets to the ground. This is perhaps more than necessary but it is such a small correction that it seems hardly worth discussing.

Then, again, we must correct for variations in fallout. It is my understanding that rather large segments of the population are subjected to rather large variations—a factor of 3 perhaps—in the variation of fallout.

I would like to evaluate V–1 and V–2. I think we can evaluate V–1, which is a variation among individuals. I think we can evaluate it quite well. Dr. Libby quite recently has described and summarized much of the available data in his speech of April 26. He concluded that the variation could be described statistically as having a standard deviation from the mean of about one-third.



What does this mean? It means that, if the population shows a normal distribution pattern, some individuals have only a little and some have a lot, but most of the people have about the average. We can describe this population in terms of the variation seen and this statistical description is the standard deviation.

If the variation in strontium 90 found in human bone does show a standard deviation which is about a third of the total average, then a value twice that average will be three standard deviations from the mean. Only a very few individuals will exceed a value twice the mean. We can say that, if the strontium data showed a normal distribution with a standard deviation of a third, and if we put a factor of 2 here for V_1, we will have only a fraction of the percent of the people exceeding the maximum permissible level. Unfortunately, I believe that the distribution is not normal. The data shown by Dr. Kulp this morning showed a skewed distribution. The natural strontium data shows a skewed distribution. It is difficult to evaluate this at the present time, but, to me, this means that the factor V_1 should be larger than 2 and probably less than 3.

I am not competent to attempt to evaluate more than crudely the variations in fallout patterns. The fallout seems to be, according to the concensus of testimony thus far, varying by at least a factor of 3. Mixing of food supplies, it is true, will dilute this effect. At the moment, for want of a better number, I will put in 3 with a stipulation that someone more competent who wishes to change that number may do so.

I think the importance of discrimination factors are now quite clear. In the equation calculating the total permissible burden for our bio-

sphere, the only number of any consequence, which permits us to live in a biosphere more contaminated than we ourselves hope to be, is the discrimination factor of 8. If we are permitted, as more data come in, to raise this discrimination factor, we automatically are permitted to raise the permissible testing rate. If as more data come in we must lower this number, then we must also lower our permissible testing rate.

I think only for purposes of illustration we might substitute these numbers and get an overall figure, since such predictions were made this morning.

Among the various MPC's that have been proposed, the number 100 was mentioned quite frequently. Actually, the National Academy of Science's report gives 2 numbers—100 and 50. The British have said that when children's bones reach a level of 10 we should worry.

Mr. Ramey. Are those sunshine units?

Dr. Neuman. These are all sunshine units or micromicrocuries of strontium 90 per gram of calcium. Therefore, we at the moment, until the discussion next week clarifies this issue, are permitted, I suppose, to choose one of these numbers.

I like 50 because this, in my opinion, would about double natural background. However, it doesn't matter. You can put the 100 in and get a number twice as big at the end.

Putting in the 50 sunshine units, just for illustration, times one-half—I will use one-half here and one-third here and 1.2 and 8. I believe that comes out to be 1.6 times 50, or 80 sunshine units on the ground as the tolerable maximal ground level.

Then the testing rate becomes 2½ percent of this—the decay rate—and that would be 2 sunshine units of annual production.

From Dr. Libby's conversion table, 1 megaton of fission equivalent is equal to 0.9 sunshine units, or we have a test rate then of approximately 2.2 megatons fission equivalent per year.

Senator Anderson. Doctor, I think I have an idea where you get the 2½ percent. Is that based on a 28-year half life?

Dr. Neuman. That is correct. If we have our maximum level on the ground and attain that level, then we can replace it at the rate at which it decays, which is 2½ percent a year.

Senator Anderson. I do not know how to express the 2.2 megaton fission. You could have a lot more power shot off—bigger bangs than that—if you had part of the process fusion.

Dr. Neuman. Yes.

Senator Anderson. When you say 2.2 megatons of fission, if you had a type of weapon that was almost entirely a fission weapon and each one of them had 20 kilotons, would you be able to shoot off 200 of them, or rather 100 of them or 110 of them, without raising the permissible level?

Dr. Neuman. The answer is implicit in this assumption of a uniform distribution throughout the world. If you shot off, as you say, 20 of the 100-kiloton devices, you would have a very nonuniform distribution, and you would have, I should think, a part of the world that would be well over its maximum tolerable level and the rest of the world well under it.

Senator Anderson. That is what I wanted to get from you.

Dr. Neuman. If you switch from one kind of detonation to another, you also change the V_2, the variation of the fallout. By the

proposed explosions that you suggest, V_2 would have to be considered much larger than the value 3 I have used.

Senator ANDERSON. In the case where we are using the Nevada proving range, the fissionable material or these products are not going to be spread equally around the world. The North American Continent will get a larger share of them, and following the wind pattern, I suppose, the area running in the northern half of the United States would get somewhat more than its share.

Dr. NEUMAN. That is correct.

Senator ANDERSON. Therefore, we would not shoot 20 100-kiloton bombs or 100 20-kiloton bombs because that would give a much greater result in the United States since you are figuring on worldwide distribution.

Dr. NEUMAN. That is correct.

Senator ANDERSON. Have you ever tried to calculate what might be a fair amount of discharge into the atmosphere taking into consideration the fact that the British and the Russians and ourselves are all doing it?

Dr. NEUMAN. I have avoided this because I don't know what the Russians have shot off. I don't even know right now what the British shot off.

Senator ANDERSON. I am not trying to involve you, so let me put it this way. I think you know that the Government of the United States through its Atomic Energy Commission has frequently announced that the Russians have exploded a certain type of device, and along with that there has generally been an announcement that sometimes is confined to the people entitled to know the capacity of that particular shot. So that the Atomic Energy Commission at least knows and probably a fair assumption is that the Joint Committee knows and the military authorities know how many kilotons each device they shoot is, plus or minus a small factor of error, and knowing that and what the British are doing and what we are doing, it would be possible to calculate pretty easily what seems to be safe.

Dr. NEUMAN. I think it is fair to say that, if we hope to choose a maximum permissible concentration of 50 micromicrocuries per gram, we have already achieved a biosphere that is fairly close to giving such a level at equilibrium.

Senator ANDERSON. We have already achieved it.

Dr. NEUMAN. I should so expect. You will recall my figures are not really very different from those of Kulp, who gave as an average number 24 micromicrocuries per gram. That is an average figure. I have already reduced the maximum permissible concentration by virtue of variation to an average level of about 25 micromicrocuries. On this basis he would have loaded bone.

Senator ANDERSON. He was going to do that at the end of 60 years. However, he was assuming a static level of testing.

Dr. NEUMAN. That is right.

Senator ANDERSON. Whereas we are in a rapidly ascending curve.

Dr. NEUMAN. He was also using a more favorable discrimination factor than I am using.

Senator ANDERSON. Yes.

Dr. NEUMAN. This is where we really get down to cases, I believe.

Mr. RAMEY. How would your figure work out if you used 100?

Dr. NEUMAN. It would exactly double the permissible rate to about 4.4 megatons per year. In terms of big bombs such as the Castle test, this figure would be one Castle test every 7 or 8 years and no other testing. If you use the maximum permissible concentration of 100 sunshine units, it would be 1 Castle test every 3½ years with no other testing, or 1 Castle test every 5 years with some additional small-weapon testing. I am uncertain about these things, but this prediction is reasonable and I am using the most reliable figures at my disposal. I think it is quite clear that we are not yet in serious trouble, but I think it is also clear that the discussions which you have scheduled could not have come at a more appropriate time—now, rather than later.

Mr. RAMEY. We were going to ask Dr. Eisenbud if he would have any comments to make on this.

Mr. EISENBUD. I believe, Mr. Chairman, that Dr. Neuman has to be complimented for introducing a new and stimulating approach which I think we will all be thinking about for the next several days. The comments, of course, must be centered on the validity of this discrimination factor of 8.

In my own approach this morning, I preferred to avoid this by going directly to milk, since we have reason to believe that the milk comes into fairly rapid equilibrium with the soil. One can thereby avoid the uncertainties involved in attempting to apply a discrimination factor in going from soil to milk and take the measurements directly. I will admit that the weakness of my approach is that I have to assume that the milk does come into rapid equilibrium with soil. This assumption I make on the basis of the evidence as it stands but it is open to some discussion.

Beyond this, I think I might welcome the opportunity later on to comment again after I have had an opportunity to give this more thought.

Senator ANDERSON. Thank you. I understand that Dr. Kulp may be on his way back and we might have some comments from him. These are at least some figures we can take a look at.

Dr. NEUMAN. May I make one more comment?

Senator ANDERSON. Yes.

Dr. NEUMAN. I must emphasize two points: (*a*) First, the testing rate, as calculated, is that which can be maintained indefinitely. Obviously, until maximum tolerable ground levels have been reached, the test rate can exceed this equilibrium value.

(*b*) Second, I am not too concerned whether the equilibrium test rate is 2, 4, or even 6 megatons fission equivalent per year. The principle I wish to establish is that a given maximum permissible concentration automatically fixes the maximum test rate and of the maximum permissible concentrations currently under discussion, none permit a test rate that is very high. The number of megatons that can be exploded is so small, some kind of international control of the production and release of fission products is inevitable.

I also want to say that even after some serious discussion, I do not think we will be off by more than a factor of 2 anyway. As I understand it, the discrimination figure of 14 was used by Kulp in his estimate. This is less than a factor of 2 from what I am using. So no matter how you slice this particular batch of data you come out with a testing rate of the order of a few megatons a year. It might be 7,

or 6, and it might be less than 2. It is not a great big number, and I think we all agree on that.

I am certainly willing to revise this as time goes on. I only wanted to get a target figure out here in the open because it is so difficult to talk in terms, "if we stop testing." We are not stopping tests. This gives us a figure of what kind of testing will result in what kind of a level in human bone.

Senator ANDERSON. I want to say to you, Dr. Neuman, I find it extremely interesting testimony, particularly since so many people keep saying to us, it is very easy to get this thing in equilibrium. All you have to do is to see that the amount of fission material you put in the atmosphere is not any greater than the amount of strontium that just naturally deteriorates.

When you ask them how much that is, they say, "Well," and that is the end of the answer. At least I have a figure here for the first time in my life.

Thank you very much. I found it most stimulating and interesting. I think it offers a possibility we will have additional discussion from other people on it.

Before Colonel Hartgering begins his presentation, I would like to insert in the record the statement by Dr. MacDonald and an article from Science magazine entitled "Strontium 90 Hazard: Relationship Between Maximum Permissible Concentration and Population Mean" by W. O. Caster, of the department of physiological chemistry, University of Minnesota:

(The material referred to follows:)

EXPERIMENTAL CONCLUSIONS PERTINENT TO CERTAIN ITEMS ON THE AGENDA OF THE FORTHCOMING HEARINGS OF THE JOINT CONGRESSIONAL COMMITTEE ON ATOMIC ENERGY ON THE NATURE OF RADIOACTIVE FALLOUT AND ITS EFFECTS ON MAN, MAY 27, 1957, WASHINGTON, D. C.

By N. S. MacDonald, Ph.D., chief, bone metabolism section, pharmacology and toxicology division, atomic-energy project, University of California at Los Angeles

Based on data from experiments performed by the bone metabolism section of the atomic-energy project, University of California at Los Angeles. Much of this work could not have been accomplished without the cooperative efforts of Dr. R. E. Nusbaum and Mr. G. V. Alexander, of the spectroscopy section of the project.

The scope of these conclusions and opinions would have been greatly broadened had the many contributions to the subjects by other authors been included. However, instead of constituting a critical résumé of the whole field, this document reviews only those pertinent investigations for which I can speak at first hand. The paragraph hearings are numbered according to the hearings outline.

POSSIBILITIES FOR WATER TREATMENT

Samples of raw and tap water were obtained from 50 cities located throughout the United States. Analyses for stable, nonradioactive Ca, Sr, and Mg were made by an emission spectrographic technique. Conventional municipal water-treatment practices involving coagulation, filtration, and softening with lime-soda ash, phosphates, or ion exchangers in some cases remove as much as 75 percent of the nonradioactive Sr normally present in the raw water of some cities. However, if the level of Sr-90 activity were more than $20\times10^{-6}\mu c$ per ml., even a 90-percent removal of dissolved $Sr+Sr^{90}$ would fail to reduce the

contamination below the maximum permissible for drinking water. In such a situation, the usual single-stage precipitation would be inadequate.[1]

THE CALCIUM MODEL AS A BASIS FOR PREDICTING SR-90 BEHAVIOR

1. Similarities and differences in behavior

The *qualitative* similarities in metabolic behavior of Ca and Sr are well documented by dozens of workers over the years. However, quantitative differences in absorption, excretion, and skeletal retention do exist.

(*a*) Double tracer studies with Ca-45 and Sr-90 on rabbits have indicated that the kidneys discriminate between Ca and Sr in the blood, with the result that *more* of an intravenous dose of Sr is excreted in the urine than is true for a dose of Ca.[2]

(*b*) Spectrographic analyses for the nonradioactive Ca and Sr always present in foods and bones have shown, both for animals and for man, that the Sr to Ca ratio of their bones is always *less* than the Sr to Ca ratio of their diet.[3] This is the result of the Ca-Sr discriminatory aspect of at least two processes operating in the chain, food to bone. These processes, where discrimination is most effective, appear to be gastrointestinal absorption and urinary excretion.

2. Influence of amount of calcium in soil, diet

The *quantity* of Sr swallowed each day does not alter the magnitude of the ratio (Sr/Ca) bone÷(Sr/Ca) diet. This implies that a permanent increase of the Sr-90: Ca value of a daily diet would result in an increase of the Sr-90: Ca value in the skeleton. Conversely, a decrease in dietary intake of Sr-90 would probably lead to a *slow* drop in skeletal Sr-90 contamination. There is apparently no upper limit to the amount of Sr which can be deposited in the skeleton.[3][4] There does seem to be an upper limit to the amount of yttrium (and presumably the rare earths) which bone can take up.[5]

The quantity of Ca swallowed *along with* a dose of Sr-90 does affect the amount of Sr-90 which ends up in the skeleton. There is a clear-cut reduction of Sr-90 bone burden as the Ca content of the Sr-90 contaminated meal is increased. (This is not true if the Ca is in the form of milk. Milk tends to *increase* the absorption of an oral dose of Sr-90.) Unfortunately, addition of larger and larger amounts of Ca do not result in *equally* smaller and smaller bone burdens of Sr-90. Addition of phosphate, sulfate, or any of a number of other substances tested, to the Sr-90 contaminated meal also reduces the resulting bone burden, probably because of a precipitating action in the gut and stomach.[6][7]

It is probable that supplementation of a meal with calcium phosphate or sulfate tablets would somewhat reduce the absorption and retention of any Sr-90 in the meal. However, the nutritional and toxicological aspects particular in infants, of any such *long-continued elevation* of dietary Ca and/or phosphate demand very thorough investigation.

In regard to the hypothetical situation where, in an extreme emergency, it might become necessary to eat 1 or 2 Sr-90 contaminated meals, a short, prior period of starvation does not necessarily make the meal more dangerous than if eating had been normal up to that time (rats). Also, consumption of large quantities of milk along with the usual solid diet, either for 2 weeks prior to a single, oral Sr-90 dose or for 2 weeks immediately after dosage, fails to alter the bone burden. Apparently, if the body is approximately in normal calcium balance, large "emergency" oral intakes of Ca have little effect on bone burden, unless the Ca is present in the gastrointestinal tract *at the same time* as the Sr.-90.[8]

May I venture the following opinions?

(*a*) The intentional enrichment with uncontaminated Ca of the population diet on a routine, permanent or semipermanent basis, with the intent of reducing the Sr–90/Ca ratio for human intake, is impractical and ineffectual. In particular, it might even be dangerous so to enrich cow's milk destined for bottle-fed infants.

(*b*) On the other hand, it is essential to ensure that the daily Ca intake of the population, and particularly growing children, is maintained at an *adequate* level *prior* to an anticipated exposure to suddenly elevated Sr–90 contamination of foodstuffs. This follows from evidence in the literature that animals whose diet has been inadequate in Ca over a prolonged period will absorb more of an oral dose of Ca (and presumably Sr–90) than animals whose nutrition has been adequate.

(*c*) If, after a Sr–90 accident, it is learned that Sr–90 has been inadvertently swallowed or inhaled (the sputum becomes contaminated and is swallowed), oral administration of epsom salts ($MgSO_4$), sodium sulfate, or calcium phosphate, within the first hour, should decrease its absorption.[9] Milk should *not* be given—contrary to lead-poisoning procedure. We have preliminary evidence, in rabbits, that *immediate massive* infusions of sodium chloride or calcium gluconate may be of some slight benefit.

DEPOSITION IN MAN—VARIATIONS OF SR–90 LEVEL

For situations of daily ingestion of Sr–90 over "sufficiently long" periods of time, the Sr–90/Ca ratio should become the same in all parts of the skeleton; that is, the distribution should become uniform, on a gross scale. In 1949, we analyzed skull bone, rib, vertebra and femur specimens from each of 21 humans, aged 5 months, 75 years, for stable, nonradioactive Sr, by emission spectroscopy. In addition, 12 cadavers preserved since 1914 were also analyzed. Within any individual there were no significant differences in Sr content between the various bones, although the Sr level of all these specimens from one individual may have been high or low with respect to the average for all individuals studied. The 1914 values were not significantly different from the 1949 values, suggesting perhaps that no major change in dietary Sr/Ca ratio occurred during this span of years.[10] What constitutes a "sufficiently long" time for this attainment of diet-bone equilibrium remains to be determined. It may be much longer for adults than for children.

As to the ultimate site of residence for Sr or Sr–90 within the skeleton, X-ray diffraction evidence indicates that these atoms finally become incorporated into the internal structure of the tiny crystals of bone mineral, possibly occupying lattice positions which normally would be filled by Ca atoms.[11] This suggests that effective removal of Sr–90 which has been in the bones for more than a short time is possible only by dissolution (resorption) of the bone mineral itself. Although such resorption and reformation of new bone is going on to some extent all the time in our bones, to hasten these processes artificially to any useful degree, is almost impossible and medically very hazardous to attempt.

PREDICTED OCCURRENCE FROM WEAPONS TESTS HELD PRIOR TO 1957

For a number of years we have studied the relationships of the stable, nonradioactive, natural Sr which has always been present in tiny amounts in all our food and in all our bones, in order to set up a model for *predicting* the behavior of the Sr–90 which is now entering our lives. Recently, samples of soils; human foods such as milk, vegetables, fruit and eggs; feeds for cows and hens; and human ribs have been collected from six widely separated regions of the United States, by Mr. G. V. Alexander and Dr. R. E. Nusbaum. They are now analysing these materials for nonradioactive Sr and Ca. The study is not complete, but one of the tentative results is that the value for

$$(\text{Sr/Ca})\ \text{cow milk} \div (\text{Sr/Ca})\ \text{cow feed} = 0.13$$

Now to arrive at a value quantitatively expressing the fate of Sr as it goes from our food to our bones, it is necessary to know what fraction of our total Ca intake comes from dairy products, what fraction from vegetables, from cereal grains, eggs, etc. This follows from the fact that Sr "travels" along with Ca in the biosphere, so that, aside from *short term* exposures to early fallout material containing particulate Sr–90, inhalation of dusts, etc., our long-term, prolonged, worldwide exposures to Sr–90 will come from the same dietary sources as our Ca. From published data, we estimate that about 72 percent of the total Ca intake for the whole United States population comes from milk and derived products and about 28 percent from vegetables, cereals, fruits, and eggs. The results on the aforementioned samples which have been analysed thus far, yield the following result:

$$(Sr/Ca) \text{ human bone} \div (Sr/Ca) \text{ average diet} = 0.14$$

Using this nonradioactive, natural strontium relationship as a model for predicting Sr–90 behavior, we feel justified in saying that, at *equilibrium* on a *fixed level* of Sr–90 contamination, the average Sr–90 activity per gram of Ca in the bones of the whole population will, in time, attain a value of about 0.14 or one-seventh that of the diet. This number is subject to adjustment, since the work is not yet completed.

Application of the natural, nonradioactive Sr model to levels of Sr–90 contamination now existing.

The following values have been taken from the report on "Sr–90 in Man," by J. L. Kulp, et al., which appeared in Science, February 8, 1957, 125, page 219 (1957):

(*a*) Average worldwide content of total body burden in man equals 0.12 micro-microcuries per gram of skeletal calcium.

(*b*) Young children have 3 to 4 times the concentration mentioned above.

(*c*) In 1955, the average diet for the human population in the United States had a burden of about 7 micro-microcuries of Sr–90 per gram of calcium.

Using our factor from natural Sr for diet to bone of 0.14, if this level of 7 $\mu\mu c$ remained fixed, we would predict that the attainable average bone burden would be (0.14) (7)=1 $\mu\mu c$ of Sr–90 per gram of Ca for the whole population. The burden actually observed was 0.12 suggesting that the bones of humans are not yet in equilibrium with the present dietary level of contamination. There is no *direct* information, derived from actual experiments, to tell us how much time will be required for the population to reach this equilibrium.

None of the work presently underway here (UCLA) gives data directly pertinent to establishment of a maximum permissible concentration (MPC) for Sr^{90} in humans. The National Committee on Radiation Protection (National Bureau of Standards Handbook 52) has proposed a total body burden for adult individuals of 1 microcurie, which is approximately an MPC of 1000 micromicrocuries per gram of skeletal Ca. However, when dealing with whole populations, exposures are likely to be distributed approximately according to a normal, statistical distribution curve. Therefore, if an average MPC of 1000 $\mu\mu c$ per gm of Ca were adopted for that population, and conditions so arranged that the *average* exposure did not exceed this, a considerable number of individuals would incur an exposure of 10 times this average. Therefore, it has been suggested that the MPC be lowered to 100 $\mu\mu c$ per gm of Ca, for controlling a populationwide contamination hazard.

Using this lower MPC, the *present* worldwide average of Sr^{90} in humans is .12 or about one eight hundred and fiftieth the population MPC. The present burden in children is one three-hundredth to one two-hundredth the population MPC. The populationwide average *equilibrium* burden to be reached some time in the future, if the present dietary level remains unchanged, will be one one-hundredth the population MPC.

Put in another way, assuming an average daily intake in the United States of 1 gram of Ca per day, members of the population could "safely" swallow $100 \div 0.14$ or 714 micromicrocuries of Sr^{90} in their daily diet throughout a lifetime. This radioactivity amount to about $714 \times 10^{-6} \times 3.7 \times 10^{4} = 26$ disintegrations of Sr^{90} per second. The present level of dietary intake is reported to be 7 micromicrocuries or one one-hundredth this estimate of the tolerable amount (with so many uncertainties, the quotation marks need for further comment).

One further speculation may be made on the basis of our natural Sr data. We know that the cow discriminates against the natural Sr in her feed during the overall process, feed to milk. That is (Sr/Ca) milk $\div$ (Sr/Ca) feed=0.13. This probably applies to Sr^{90} also. Therefore, one can estimate the Sr^{90} getting

into the human diet via milk products, by monitoring only the cow feed. This obviates the overwhelming task of monitoring all the multitudinous dairy products destined for human consumption. All such products should have a Sr^{90}/Ca concentration of about one-seventh to one-eighth that of the cow feed, unless intentionally enriched by addition of uncontaminated mineral Ca.

[Reprinted from Science magazine, June 28, 1957]

Strontium 90 Hazard: Relationship Between Maximum Permissible Concentration and Population Mean

Recent discussions of radiation fallout (1, 2) have related the population mean Sr–90 body burden to the maximum permissible concentration, or MPC. Libby (1) has introduced the "MPC unit" (1 uc of Sr–90 per kilogram of calcium) and has used it to express concentrations of Sr–90 in milk, plants, soil, and so forth. The direct comparison of any mean with MPC, of course, implies that the two different terms are expressed in comparable units. Unfortunately, this is not true. The MPC unit represents the maximum permissible concentration of Sr–90 within the body that may be considered safe for any individual—and the individual is assumed (3) to be a professional isotope worker, probably male, 45 or more years of age, who is exposed to the isotope only under rigidly controlled laboratory conditions. A population mean, on the other hand, does not represent a maximum value, but rather a value which, by definition, will be exceeded by 50 percent of a population.

How much of a quantitative difference results from this inequality of units of expression? One example may suffice. In discussing the Sr–90 burden in a general human population, at least three additional factors must be taken into consideration: S, a safety factor; C, an allowance for children; and H, a heterogeneity factor. Thus,

$$MPC_{pop.} = \frac{MPC_{oc.}}{SCH}$$

where $MPC_{pop.}$ is the maximum permissible concentration that would be safe for a population mean, and $MPC_{oc.}$ is the maximum permissible concentration for occupational isotope workers (1 μc of Sr–90 per kilogram of calcium, 3).

Because of the uncertainty in the figures for maximum permissible concentration, it is usually suggested that members of the general public should not be exposed to more than one-tenth of the radiation hazard that is permitted for occupational workers (4). The value of S is therefore taken to be 10.

Kulp, Eckelmann, and Schulert (2) showed that children (0 to 4 years old) accumulate Sr–90 more rapidly than do adults (40 to 60 age group). The concentration of Sr–90 in the bones of children averaged 4 to 5 times that found in the general population (and 10 percent of the children exceeded this figure by a factor of (twentyfold or more). Added to this differential accumulation factor is the factor of the increased vulnerability of this age group. This factor is difficult to evaluate without direct experiments. It can be pointed out, however, that children in this age group have over twice the expected life span ahead of them in which to develop neoplastic or bone calcification changes in response to radiation exposure. For the moment, C is taken to be 5 x 2, or 10.

Within the 10 to 80 age group, there is a substantial variation in body burden of Sr–90 for people in one area, who are presumably exposed to the same environmental Sr–90 concentration. This may be related to differences in food habits, idiosyncrasies of calcium metabolism, and other factors. From the data of Kulp, Eckelmann, and Schulert (2) one can estimate that 6.8 percent of this population group will have a body burden of Sr–90 which exceeds by at least fivefold the population mean value for that age and area, 1 percent will exceed its population mean by about tenfold, and 0.2 percent will exceed its own population mean by more than fiftyfold . It is evident, therefore, that H must exceed 10. Combining these terms, one would estimate that:

$$MPC_{pop.} \leq \frac{1\ \mu c\ \text{Sr–90/kg Ca}}{10 \times 10 \times 10} = 1\ m\mu c\ \text{Sr–90/kg Ca}$$

A comparison of this figure with estimates (1, 2) of the Sr–90 concentration in man leads to the conclusion that the Sr–90 burden in the general population in 1955 was at least 10 percent of the $MPC_{pop.}$, and that if the predictions (1, 2) concerning the next 10 to 15 years are correct, the population mean value will shortly reach and exceed the maximum level compatible with public health and

safety. This view gives a very different picture of the probable safety situation from the one obtained by a direct comparison of MPC_{oc}. and the population mean (1, 2) and points to the hazards of introducing novel units of expression without first considering their fundamental nature.

Meanwhile, if any simple safety measures are available, advantage should be taken of these without delay. Since some 80 percent of the dietary calcium (and thus Sr–90) that enters the body comes from milk and milk products (5) it would seem possible to decrease the intake of Sr–90 by declacifying milk. Such a procedure is reportedly effective (6). The technology and economics of this process are essentially those used currently in the production of low-sodium milk (7) and in a process for soft-curd milk (8). Milk calcium could then be replaced by calcium derived from ancient sources (limestone, for example) which would have a much lower Sr–90 content. This procedure would not seriously disturb the calcium balance in the general population, and it could provide an immediate four- to five-fold reduction in the intake of Sr–90.

STATEMENTS OF LT. COL. JAMES B. HARTGERING,[2] MC; ACCOMPANIED BY LT. ARIEL G. SCHRODT, MSC, WALTER REED ARMY INSTITUTE OF RESEARCH, WALTER REED ARMY MEDICAL CENTER

Colonel HARTGERING. The Walter Reed Army Institute of Research has been engaged in measuring the worldwide fallout from nuclear tests since 1954. Following the radiation exposure of American military personnel to the March 1, 1954, detonation in the Pacific area, Walter Reed Army Institute of Research personnel had the opportunity of participating in their medical evaluation at Tripler Army

[1] Public Health Service Research Fellow of the National Heart Institute.

Hospital in Hawaii. As a part of the evaluation, urine specimens were analyzed for radioactive fission products. Routine control specimens were collected from residents of Honolulu and Washington, D. C., and it was determined that these contained about the same amount of iodine 131 activity as urine collected from the servicemen exposed to local fallout in the Marshall Islands.

Prior to 1955 a number of scientists in the United States as well as other countries had measured nuclear debris using air filters, gummed paper, and soil sampling techniques. Professor Libby and others had measured the strontium content of human bones and a few human fetuses. Extrapolations were made estimating the expected levels of fission products in contemporary man, but many technical uncertainties prevented other than gross figures. No direct data was available for the accumulation of specific isotopes in the average individual as he goes about his daily routine.

It appeared to us that the uncertainties of extrapolation of physical data to man were so great, and the problem of such fundamental importance, that direct measurements of large numbers of men should be attempted. The fact that United States military personnel are stationed throughout the world provides an ideal sampling network.

It is known from animal and limited human data that many fission products are excreted by the kidneys and appear in the urine of exposed individuals in amounts that can be predicted, provided the excretion rate for the individual isotope being studied is known. Therefore, it was decided that the measurement of radionuclides present in 24-hour urine specimens could result in direct evidence of the amount and type of activity present in man.

EXPERIMENTAL DESIGN

In January 1955, with the cooperation of active duty military personnel stationed as indicated in figures 1 and 2, a sampling network was selected. At each United States station, 10 individuals participated and at overseas stations, 5 individuals. Twenty-four-hour urine specimens (1–2 liters) were collected by each individual in the United States once a week for 14 weeks during Operation Teapot and shipped by air to the Walter Reed Army Institute of Research. Foreign stations contributed on a reduced schedule. In excess of 2,100 specimens from the 17 United States stations, and 500 from the 15 overseas stations, were received and processed. Isotopes of iodine, strontium, and cesium were separated radiochemically and the levels of activity determined by low-level beta and gamma counting techniques.

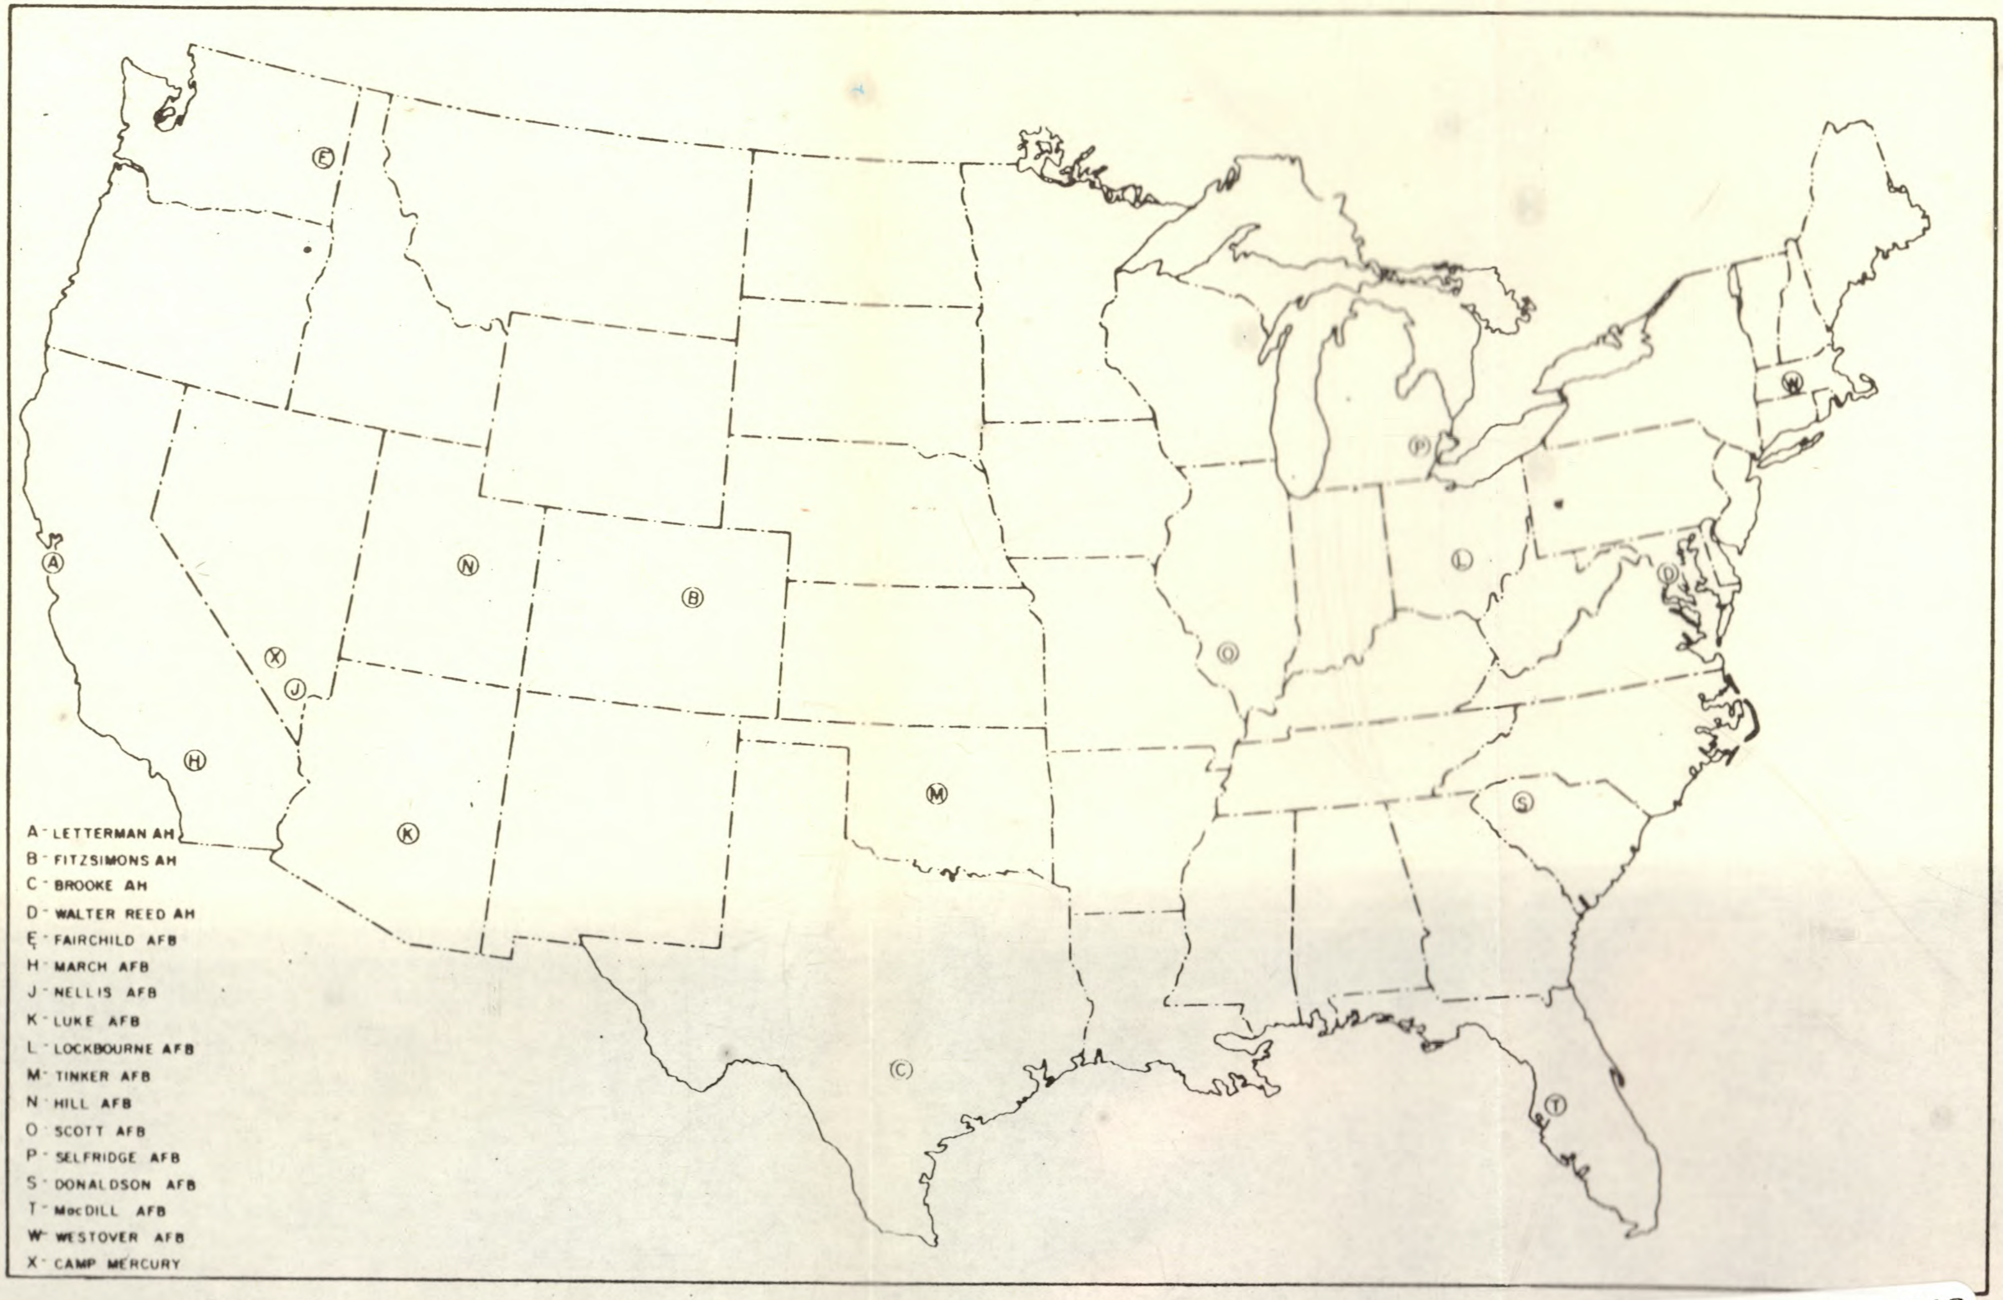

FIG I MAP OF US COLLECTION STATIONS

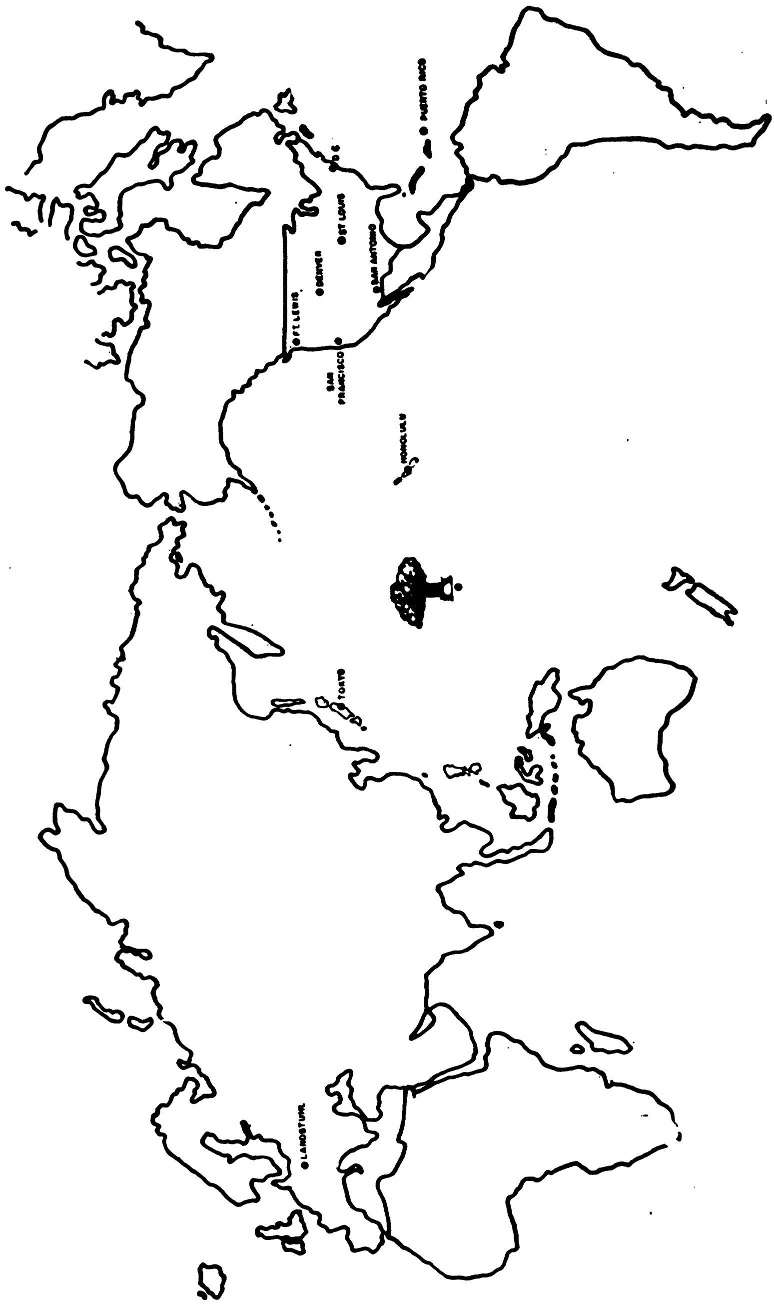
93299 O - 57 - pt. 1 (Face p. 726)

In March 1956, prior to Operation Redwing, a different network (fig. 3) was established after consulting Dr. L. Machta of the United States Weather Bureau. The number of stations was necessarily reduced because the proposed radiochemical procedures were expanded to include, in addition to the isotopes mentioned above, specific determinations for the presence or absence of zirconium 95, ruthenium 106 and whatever other nuclides might be unexpectedly present. Again, in excess of 2,000 specimens were received and processed.

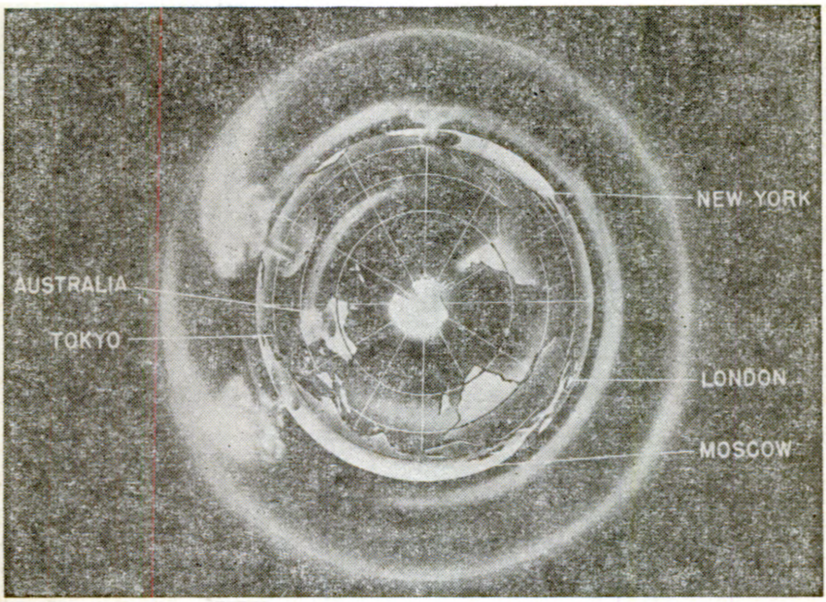


COLLECTION STATIONS

RESULTS

Figure 4 is a schematic representation of the tropospheric and stratospheric distribution of radioactivity following nuclear detonations. Since in this study we are measuring man directly, the values obtained represent the total fallout accumulated in and available for assimilation into the human system at the time of sampling, irrespective of its source. In view of the long estimates for stratospheric storage time (half time of 7–10 years) and the short physical half life of iodine (8 days), it is perhaps apparent that much of the activity measured in the urine specimens was tropospheric in origin.

FIGURE 4



Figures 5 to 13 are examples of the positive data obtained. Iodine values represent the average activity of the 10 or so individual specimens submitted from the specific station on the date noted. Values are corrected for decay to the time of collection. The values among individuals at the same station differed by as much as a factor of 10, but this is within the expected biological variation. The cesium and strontium values were determined by pooling specimens from one or more weekly collections at a given station. Pooling was required as the expected activity was so low as not to be otherwise detectable, even with the very sensitive low level counting equipment at the Walter Reed Army Institute of Research. Strontium values are available only for the first 6 weeks of the Redwing (April–September 1956) study. The remaining samples are currently being processed. Cerium 144 is known to be present in the 1956 specimens, but the actual amounts are as yet undetermined. Detailed radiochemistry failed to reveal the presence of either zirconium or ruthenium.

COLLECTION DATE

The generally rising levels of specific activity during each test series are noted in most of the figures. In addition certain peak values are apparent, particularly for iodine and cesium. These rises, in general, correspond to the presence of a specific radioactive airmass over or near the sampling station. Airmass trajectories were obtained from Dr. L. Machta and are represented by (X's) at the appropriate altitude as measured in thousands of feet. The correlation between abrupt peaks of activity in man and the presence of an active airmass is quite good. Further, negative urine data obtained during Operation Teapot, at other stations not shown in the figures, such as Letterman Army Hospital, San Francisco, and Westover Air Force Base, Mass., helps to strengthen this correlation. In our opinion the peaks, particularly for iodine, but also for cesium and perhaps strontium, are due to inhalation of the radionuclides and do not reflect transmission through the food cycle. No doubt the plant animal-food cycle also contributes to man's radioactivity, but at early times we would suggest that inhalation may be the primary entry route for certain isotopes.

Utilizing known average excretion rates for iodine and cesium in man, our urinary values can be converted to estimated body burdens for Operation Teapot (1955). The maximum average iodine thyroid values were obtained from Ogden, Utah, and were 11×10^{-4} microcuries per individual. For Redwing (1956) the maximum was at Denver, Colyo., where the average thyroid burden was 13×10^{-5} microcuries. It is emphasized that these are maximum values and represent respectively 1/10,000 and 1/100,000 of the amounts given as tracer doses to patients in radioscope clinics throughout our country.

The maximum cesium body burden for Redwing was obtained from Washington, D. C., and was 3.4×10^{-3} microcuries. This may be compared to the proposed tolerance value of 30 microcuries.

Available strontium excretion values for general locations are noted in figure 14. The urinary excretion rate for man can only be estimated at the present time, but a conservative figure would indicate a body burden of the order of 1 to 5×10^{-3} microcuries as compared to the general population tolerance of 0.1 microcurie.

CONCLUSIONS AND RECOMMENDATIONS

The data obtained in this program by measuring in excess of 4,600 24-hour specimens indicates that several fission products are readily detectable in man. Estimated body burdens for individual isotopes were several orders of magnitude below currently acceptable tolerance limits. Incidently, our values agree, in general, with those measured by other laboratories and by other methods.

Strontium values

Area	Year 1955	Spec. No.	DPM/spec.

Denver, Colo.	do	61	.30

This is to our knowledge the first example of such an extensive sampling program in the field of medicine and establishes the fact that the levels of the various fission products can be readily determined in the world's population by directly measuring man himself. This method avoids any uncertainties inherent in extrapolations from purely physical or animal data to man, and should provide an additional assurance that, in fact, the nature of current radioactive fallout is understood in considerable detail. Further, we believe that the methodology used in this program could, if desired, be expanded and employed as a continuing positive check on the status of worldwide fallout. If indeed, the radioactivity in man began to increase in any part of the world, it could be recognized immediately and appropriate precautionary measures taken before significant levels of activity were reached.

As is often the case in the study of medicine, however, a considerable amount of painstaking research still needs to be completed before we will be in complete control of the atom and its possible effects on man. The obvious gaps in our medical knowledge today are in the following three areas:

(*a*) The requirement for a more complete understanding of the kinetics (uptake, distribution in the body, and excretion rates) of the isotopes now known to enter the body.

(*b*) The somatic effects of the combination of the several isotopes on man. Current tolerances are established for individual isotopes, and it is assumed that the effects are merely additive, but detailed information is not yet available.

(*c*) A long-term continuing evaluation of the actual effects of these isotopes on man so that factual tolerance values can be established.

As research continues in these and other areas and the details become more completely understood, it is entirely possible that, in addition to physical methods, certain preventive medical measures may become available which will reduce the possible accumulation of even low levels of isotopes in man. I would like to point out that preventive research in nuclear medicine is really just beginning at the present time and a considerable degree of optimism is, in my opinion, justified.

Mr. Ramey. Does your work mean that individuals then pick up strontium by breathing from the air?

Colonel Hartgering. That is right.

Mr. RAMEY. As well as from food and milk, and so on?

Colonel HARTGERING. We feel that our data shows this without question, sir.

Mr. RAMEY. Is the amount they pick up significant in relation to these other amounts?

Colonel HARTGERING. This is a very difficult question to answer because it depends on the location of the individual. For an individual who is working for the Department of Defense or the Atomic Energy Commission at the test site, the amount that he picks up during the test period is significant. For the individual several thousand miles away this is just a part of it, and maybe it is a small fraction of the total that he will pick up over the next period of time. In our opinion the peaks particularly are due to the inhalation and do not reflect transmission through the food cycle. No doubt the food cycle is important and also contributes to man's radioactivity at late times.

Mr. RAMEY. Doctor, are the methods that you have used such that they are readily adaptable to monitoring strontium in bone?

Colonel HARTGERING. The methods we used are the same as Dr. Kulp uses in measuring the amounts in bone. We start out with several gallons of liquid urine and reduce it to a small volume and do essentially the same chemical separation and measuring procedures that he uses.

Senator ANDERSON. Thank you very much. This has been a very interesting discussion. I certainly commend you on the work that is being done in the field. It is very encouraging.

Now we come back to where we should have started this afternoon had we been able to stay on schedule: Dr. Langham and Dr. Anderson of Los Alamos Scientific Laboratory.

STATEMENT OF DR. WRIGHT LANGHAM,[1] ACCOMPANIED BY DR. E. C. ANDERSON,[2] LOS ALAMOS SCIENTIFIC LABORATORY

(A comprehensive report by Dr. Langham and Dr. Anderson on the hazards of strontium 90 appears on p. 1348.)

Dr. LANGHAM. The remarks that I plan to make, I would like to limit to a consideration of the long-term fallout problem in preference to getting involved in the discussion of what might be the result of

[1] Received a bachelor of science degree in science from the Oklahoma A. and M. College at Goodwell, Okla., in 1934, and a master's degree from the Oklahoma A. and M. College at Stillwater, Okla., in 1935. From 1935–37 he held a position of research chemist with the Agricultural Experimental Station at the Oklahoma A. and M. College at Goodwell. From 1937–38 he did graduate work at Iowa State College, Ames, Iowa, working in the field of organic chemistry. From 1939–41 he returned to the Agricultural Experimental Station at Goodwell, Okla., as acting experiment station director. In 1941 he entered the University of Colorado, from which he was awarded a doctor of philosophy degree in biochemistry with a minor in biology in 1943. In the same year he joined the staff of the Manhattan district's metallurgical laboratory at the University of Chicago, where he worked on the chemistry of plutonium. In 1944 he was transferred to the Los Alamos Scientific Laboratory, Los Alamos, N. Mex., to study the toxocology of plutonium and to develop methods of diagnosing exposure of personnel to this material. In 1946 he became the group leader of the biological and medical research group of the laboratory. Since then he has investigated a number of major problems concerning the biological and medical aspects of atomic energy development. These include rates of retention and excretion of internally deposited radioactive isotopes, toxicology, and physiology of tritium in man, relative biological effects of ionizing radiations of different types and energies, including bomb gamma rays and neutrons, incapacitating effects of massive doses of radiation, hazards from accidental noncritical detonation of atomic weapons, and the biological and medical implications of worldwide radioactive fallout. He is at present group leader of the biomedical research group and assistant division leader (for research) of the Los Alamos Scientific Laboratory's Health Division, and is an associate professor of biochemistry with the University of California at Los Angeles. He is a member of the following committees and organizations: Subcommittee on Internal Tolerances of the International

shorter-term fallout in the event we are actually involved in a nuclear war.

If we look over the fission products and the radioactive debris that results from weapons detonations, we find we can immediately eliminate the majority of the fission products as a long-term hazard on the basis of their physical half-life, their biological half-life, or the degree to which they enter into the ecological cycle.

Further inspection of these results indicate that there are really only three which might be of serious consideration. One is plutonium 239. It has not been mentioned in this meeting perhaps, but every time a bomb has been exploded it has probably made about as much plutonium as was burned up in the detonation. Therefore in these atomic clouds we do have plutonium.

We have only two other isotopes of appreciably long half-life which have a possibility of being hazardous. Those are strontium 90 and cesium 137. Let us dispose of the plutonium problem first.

Plutonium is a manmade element, at least in any great abundance. It is not taken up by plants and the discrimination factor is going from soils to plants for plutonium is a matter of 10,000. Plutonium is extremely poorly absorbed from the gut. The discrimination in this case is another factor of ten to the fifth or a hundred thousand.

Then we can immediately say that the concentration of plutonium in the bones of the individuals will be only of the order of one-one hundred millionth of what it is in the soil.

Knowing the amounts of plutonium that are made in these detonations, it is immediately possible to eliminate plutonium for any further consideration in the long-term fallout problem.

Let us now come to cesium 137. When a bomb is detonated the fission products form at various stages after the detonation. Cesium 137 and strontium 90 are formed with a halftime of about 3 minutes, which means they are formed late in the history of the fireball. Consequently, they are not trapped as much as are other isotopes in the heavy debris which falls out locally.

Since they are formed at approximately the same times in the history of the fireball, cesium and strontium tend to go together. So where we find one, we will find the other; in approximately the ratio they occur in the fission mixture, which is almost 1 to 1.

Then every time we have a millicurie per square mile of strontium 90, we will have a millicurie per square mile of cesium 137 deposited.

In order to evaluate the cesium 137 hazard, let us refer to natural potassium. The body contains approximately 150 grams of potassium. This is vital to life. Potassium, however, is radioactive, having in it

(Submitted by Atomic Energy Commission.)

the isotope potassium 40. The number of gamma disintegrations occurring from potassium in the human body is approximately 450 per second.

In other words, from the natural potassium in our bodies, we are absorbing 450 gamma disintegrations per second. The number of beta disintegrations are approximately 9 times higher.

So therefore, we are getting somewhere around 9 times 450, which is about 4,000 beta disintegrations per second from potassium.

All of this is equivalent to approximately a tenth of a microcurie of activity. The amount of activity, taking into consideration the absorption factors in tissue, will result in our receiving a radiation dose of approximately 20 milliroentgens per year. This constitutes approximately 20 percent of our natural background of 100 milliroentgens per year.

When we measure, using the human counter at Los Alamos and the crystal counter at the Argonne Laboratory, the cesium to potassium ratio in people, we find that this ratio is approximately 0.05, meaning, then, that the amount of radiation that we receive from the cesium in the bodies of people as a result of weapons testing so far, is about one-twentieth of what we receive from the natural potassium background level.

The present concentration, then, of cesium 137 in people is contributing approximately 1 milliroentgen per year. It is of interest, of course, to everyone to consider what about the genetic dose. Since it is pretty well established that we have had to and will continue to live with background, the question then becomes one of whether cesium 137 concentrates in the gonads imposing on the population a genetic dose out of proportion to the 1 milliroentgen per year delivered to the total body?

Analysis of the gonads of animals injected with cesium 137 show there is no concentration above normal in these organs. The principal site of concentration of cesium 137 is the same as that of potassium—the muscle. So we might expect muscular people to have a little more cesium than do fat people. We might expect men to have more than women and variation in cesium 137 over the country is but not more than a factor approximately 2 or 3 at most. The dose that we receive to our gonads as a result of cesium 137 fallout is, therefore, approximately equal to the dose that we receive to the rest of the body. We can say with confidence that cesium 137 is increasing our gonad dose by 1 milliroentgen per year, which is again approximately only 1 percent of the radiation dose our gonads receive from natural background.

This, then, definitely says that it is hard to imagine cesium 137 being either a genetic threat or a somatic threat, unless we can say that continued weapons testing or fallout from the stratosphere is going to increase this level by manyfold. Cesium 137 when it falls upon the soil becomes tightly bound and associated with the soil colloids and cannot be leached off very readily and consequently is not taken up by plants except perhaps to the extent of 1 percent. So at most the concentration in the plants we eat will be only about 1 percent of the concentration in the soil.

Another question, then, might be, is it possible that this material, as is the case with strontium 90, concentrates in the bone or in some

tissue from which it has a very slow biological turnover time. Using human subjects we have measured the turnover time of cesium 137. There measurements show that it concentrates in the muscle and the muscle constitutes a major portion of the body mass. Therefore, it is not concentrating a great amount of radiation in a small volume of tissue.

When we measure the cesium 137 turnover time in people, we find that half of it is disappearing every 110 to every 140 days. Then there is no long-term highly concentrating mechanism in the body. We can assume that if weapons tests continued at the present rate, the cesium 137 level in people, which is in reality a measure of the amount of cesium that is falling out in any given period of time and not the total integrated amount of cesium, will remain essentially constant with a constant weapons test rate.

If we accelerate the test rate, we will increase the level of cesium 137 in people by a proportionate amount to the amount of fission that is involved in the weapons tests.

Remember, we are not talking about megatons of explosive yield in this problem. We are talking about the megaton equivalents of fission products put into the biosphere. We can explode bombs with a greater thermonuclear component (and no greater fission component), thereby increasing greatly the yield of weapons fired, and not increase greatly the amount of fission products added to the biosphere. It is my understanding that Dr. Neuman's number of 2.2 megatons per year is referring to fission yield injected into the biosphere, and nct yield of total explosive force fired.

Mr. RAMEY. When you say "we," you mean the United States. That would not necessarily mean some other country that was just learning how to make bombs?

Dr. LANGHAM. Anybody who is firing atomic weapons is being referred to, or should be, in terms of the amount of fission products that he puts into the biosphere, not the total yield of his weapon.

Mr. RAMEY. I understand that. I meant in relation to getting more explosive yield with less fission through some mechanism.

Dr. LANGHAM. Getting more explosive yield through less fission is in all probability what any country will be doing.

Senator ANDERSON. We did not do it the first year we started our work. Did we not wait a few years and gradually develop into this and therefore do you not think other countries not as advanced may do the same thing we did?

Dr. LANGHAM. We have a pretty good idea that the British and Russians are already doing the same as we did. In other words, the thermonuclear yield or the thermonuclear weapons tested both by the Russians and British are an attempt to get more yield which involves less fission.

Senator ANDERSON. I think we would all agree to that. It is a fusion type to a great degree.

Dr. LANGHAM. It doesn't matter whose weapon it is. The thing that is of critical importance is not the total yield of the weapon from the point of view of the problem we are discussing, but how much fission they had to employ in order to get that yield.

Senator ANDERSON. You did not think Dr. Neuman did not understand that, did you?

Dr. LANGHAM. I do not know whether he did or not. He said megatons of bombs.

Senator ANDERSON. No; he did not. You were not following him very closely. He had exactly the same definition you used.

Dr. LANGHAM. That is fine. What I want to say is that this does not mean—and I want to be sure that the audience understands—that 2.2 megaton yield is the limit to the amount of testing that we can do. It is 2.2 megatons of fission yield injected into the biosphere.

Senator ANDERSON. I though Dr. Neuman made it clear, and I am glad you did also.

Dr. LANGHAM. Then I am sorry. This, then, will bring us to the point where I think we can say that the cesium 137 problem is certainly and will remain secondary to the strontium 90 problem. This makes, of course, the strontium 90 problem considerably more interesting and focusses attention in the cesium 137 work on using cesium 137 to study the mechanisms whereby radioactive fission products are distributed in the biosphere. It is for that reason that studies in this direction certainly should continue. It is very possible that cesium 137, or what we learn by cesium 137 until it hits the ground and begins to enter the ecological cycle, can tell us a great deal of what happens to strontium 90 before it hits the ground.

Cesium 137 is much easier to measure than strontium 90. So we may be able to collect considerably more data on strontium 90 by inference to cesium 137 work.

We have just received a phone call from Dr. Rose in Chicago who asked us to read something into the statement that he entered into the record with regard to the cesium 137 problem. Dr. Marinelli and Dr. Rose have just measured the cesium 137 content in a number of people from South America. Their result indicates that the average found in those people was about 14 micromicrocuries of cesium per gram of potassium, and that compares to the measured value in the United States of 34; 14 versus 34. This signifies, then, that if strontium and cesium do indeed go together, then there is a factor of 2 difference between the fallout in South America and the fallout in the United States. This would indicate again what you have heard voiced many times today, that despite the fact that one might think of great variations over the face of the earth, these variations do seem to be confined to factors of 2 and 3. This is a very important point.

As far as I am concerned, this is what we have to say with regard to the cesium 137 problem. I would like to mention the strontium problem insofar as we see it and perhaps add a little more to what has already been said, with regard to equilibrium levels, and its relation to the present test rate.

First I would like to put down the numbers that have been quoted variously, and some of them here today, for the estimated strontium 90 level in the bones of people at the point of maximum fallout which will be in about 1970 or 1975, and really show you how these values agree.

Dr. Libby in his recent speech has estimated that the level would be from 1.7 to 2.5 micromicrocuries of strontium 90 per gram of calcium at equilibrium, assuming no more weapons tests. This estimate was made on the basis of ecological data, assuming a discrimination factor

of from about 20 to about 30, somewhat in disagreement with the discrimination factor you have heard expressed by Dr. Neuman.

Senator ANDERSON. May I ask, is that a comparable figure to the figure of 8 which he was using?

Dr. LANGHAM. That is right.

Senator ANDERSON. 20 to 34?

Dr. LANGHAM. 20 to 30.

Dr. Kulp in his recent article—and I am talking now about the United States of America and the upper northern section, the section that is supposed to have the most fallout—made an estimate of approximately 2 $\mu\mu c$ per gram of calcium, again based on ecological considerations.

We have made estimates at Los Alamos on the basis of ecological factors also. The average equilibrium level for the United States we come out with as 3.1. We have taken Dr. Kulp's bone data and made a correction that we think is justified. I have not discussed it with him. On that basis we come out with 3.2 for the equilibrium level for the upper United States.

Dr. Eisenbud in his consideration this morning, talking about New York, estimated an equilibrium level of 4.1. We have also derived a value from milk data by merely taking not the average for New York but the average for Chicago, New York, and other milksheds, and we obtain a value of 3.5.

I think it is amazing that we do get agreements this close together when these are derived by different means. The thing perhaps we should be considering is the average for the population belt of the world, because the major portion of the fallout is occurring in that area which has the major number of inhabitants. If we do this, we can estimate for the area between 10° N. and 60° N. latitude, approximately 2.5 micromicrocuries of strontium 90 per gram of bone calcium. These are average values for the area.

Senator ANDERSON. Are all these figures based on no more testing?

Dr. LANGHAM. These are all based on no more testing; yes.

Senator ANDERSON. I don't understand why you start on that assumption.

Dr. LANGHAM. You must start on that assumption and it is the first step in going on to trying to estimate what will happen later. This is the reason.

We can make estimates for the entire world and obtain an average of the world population. Dr. Kulp has made such an estimate. For the entire world he has estimated a value of about 1.3. We have estimated this value by two different methods—by considering ecological factors and by using Dr. Kulp's bone data—and when we do, we come out with a value of 1.7, again amazingly good agreement.

Senator ANDERSON. Doctor, does that not also point up how accurate your observation was a minute ago? You were talking about cesium and the study that had been made in Latin America and you said Latin America it was half of what it was in North America. You said this is also very similar to the strontium figure and the strontium figure would show that, because you have a figure of 2.5 here and something like 1.3 there which is certainly comparable to the figures you had a moment ago.

Dr. LANGHAM. Thank you. I didn't notice that myself.

Senator ANDERSON. Is it accidental or does it seem to work out that way?

Dr. LANGHAM. I think as our data get better and better we are going to find these things beginning to pull together. I can remember when the arguments here were that this may be as high as 50. Now we have it narrowed down so that the disagreement is at most a factor of 2. Remember, I am talking about averages over a specific area, and there is a certain finite probability that any person or that a person or a few persons in any proscribed area will run as much as 2 to 3 times these values and I am now talking about the very factor that Dr. Neuman was introducing, his V–1 factor that he put into his equation.

On this basis, then, we can do a little more with the data as far as what does it mean with regard to present and future tests.

Let me now talk in terms of the population average of 2.5. I am talking now about the area of 10 north to 60 north latitude. Present levels are only about one four-hundredth of the workers permissible value if we want to assume that the maximum permissible level that we will permit the population in this area to reach on an average is 1,000 micromicrocuries per gram of calcium, the occupational tolerance—remember, Dr. Kulp did this some time ago and got criticized for it because it is as inferred that he was recommending we let the population do this, he was not so inferring but was merely trying to tie the values to something that we have accepted and we have accepted that the maximum permissible level for the working or occupied population shall be 1,000 micromicrocuries per gram of calcium. It is pretty well established insofar as the national and international conferences on radiation protection are concerned, that if we are including a large segment of population of nonworking people, then we should lower this by a factor of 10, which puts it to 100 micromicrocuries per gram.

Dr. Neuman has preferred to use 50 here, because of the statement that was made in the National Research Council and National Academy of Science report, in which it was merely said it may be advisable in the case of children to lower this even further.

We can now set up a simple proportionality between strontium 90 equilibrium megatons of fission to date as Dr. Kulp did, in which he took Dr. Libby's data on stratospheric storage and fallout, and he said the present situation we face must be the result of the injection of approximately 50 megatons of fission yield into the biosphere.

If this be true we set up a simple proportionality and say that 2.5 is to 50 megatons as x is to 1,000 or 100 micromicrocuries per gram of calcium, and we can calculate the number of megatons of fission weapons we would have to fire all at one time (and let them fall out at one time) in order to bring the average of the population belt up to these various levels.

When one does this, he comes out with 20,000 megatons of fission products injected into the biosphere would bring the population to an average level of 1,000 micromicrocuries per gram of bone calcium.

Two thousand megatons exploded all at once (and letting it fall out all at once) would bring the average up to 100 micrimicrocuries per gram of calcium.

Now we get into the areas of uncertainty. The things that are most important, far more important than factors of 2 difference in distribution or factors of 2 difference in the equilibrium level in people. For example, we have right here a disagreement of a factor of 10 depending on whether we use the occupational or nonoccupational permissible level. If we want to use Dr. Neuman's level of 50, we have then a disagreement of a factor of 20.

Then our major source of disagreement is on what do we dare let the level in the population reach on the average. Let us do something more with this. Let us say that a factor of 3 is enough to cover the difference in distribution and the discrimination factor. Then we would say we would want to divide this number by 3 (20,000) which would give us roughly 7,000, and in this case (2,000) would give us roughly 700, which would say we could explode 700 megatons before we would take a chance of bringing many people up to the nonoccupational exposure.

Let us assume that the tail on the stable strontium distribution curve that Dr. Kulp has presented, in which he said that it was skewed distribution. Let us take the attitude of the ultraconservative and say because this tail exists and we do not have a normal distribution we had better apply a factor of greater than 3. Some people have done this. They have said the bone data themselves, show a spread of a factor of 10. Let us introduce a factor of 10. That would mean we would have to divide the 7,000 by 10, which would give us 700, and if we divide the 700 by 10 we are now down to 70 megatons. In other words, there is on this basis at the present time a factor of about 200 to 300 disagreement between the ultraconservative and the person who dares be somewhat radical. Where does this variation lie?

A factor of 10 lies in this point where some person might say it does not hurt to let people reach 1,000 micromicrocuries, another says 100 and another says even lower.

There is another factor of 10 in what we assume for the spread in non-homogenity of distribution of this material in people and soil.

Then if we multiply 10 by 10 we have a factor of 100. So 100 out of our 200 or 300 disagreement comes in 2 points, which points out immediately, the important things for us to do.

Senator ANDERSON. Doctor, would you excuse me just a second. I do not follow you for a second there. When you have 25 over 3 you come out with 7,000. When you have 25 over 10, why don't you come out with 2,000?

Dr. LANGHAM. You are right. That is what I should come out with, 2,000 and 200. In other words, 2,000 and 200 instead of 700 and 70.

I think my statement was that the most important things for us to do is to work on what really should be the average maximum permissible level that we dare allow a large segment of the population to reach.

The second thing that we should do is continue the type of work that Dr. Kulp is doing, and others, and study by all means the distribution of strontium 90 in soils, the distribution of strontium 90 in bones, and anything which will give us a cue as to the nonuniformity aspect of the problem.

Do we divide by 10: do we divide by 3; or don't we divide at all?

The Atomic Energy Commission's research program, that of the

Division of Biology and Medicine, is pointed in this direction. What does this mean in terms of future tests?

This, as I said, was a consideration based on no more weapons testing and then firing a number of megatons and making the assumption that they all came down at once and they were all injected into the biosphere at once.

If we continue to test weapons at the present rate, and this is something that I know has worried Senator Anderson a great deal, we cannot establish yet what the increasing rate of weapons testing is. In Castle—and I do not mean weapons testing, I meant to say the rate of injection of fission products into the biosphere. It does not correlate necessarily with megatons of weapons exploded.

In Castle we exploded a lot. In Redwing we exploded quite a number of megatons of yield but less fission products were injected.

So it is hard to say that we do have any kind of an increasing rate in weapons testing which will allow us to say what we will go to if we continue to accelerate at our present rate. But we can say this: If our present situation is the result of 50 megatons injected into the biosphere and this has occurred over 5 years, then we are roughly contributing on an average about 10 megatons per year to the biosphere. If we continue at this rate, there are two numbers that one can use. Only two estimates have been made, one from the British and one by Dr. Libby.

Dr. Libby has stated that if we continue at our present rate, we will reach equilibrium at about 8 times the level that we would be at if we stopped immediately.

For the population belt we said it was 2.5 micromicrocuries per gram of calcium. If we take 8 times that, that gives us roughly 20 micromicrocuries per gram of calcium will be the average level in the people in the population belt if Dr. Libby's factor of 8 is right and if we continue to test by injecting 10 megatons per year into the biosphere.

This is not in disagreement with somebody who said 24 this morning.

Mr. RAMEY. That was Dr. Kulp.

Dr. LANGHAM. If you want to consider the United States, the United States is somewhat higher. In other words, here we would have certainly as much as 3. So 3 times 8 equals 24 which was the figure Dr. Kulp quoted for the United States.

There is one other figure. Let us enlarge this still further. If this is the average and we say we can let a factor of 3 take care of nonhomogenities, then there may be a few people who will be 3 times the average in the United States, or 72 micromicrocuries, which is getting up close to the recommended maximum level of 100.

If we want to be even more conservative and introduce a factor of 10, then we must multiply 24 by 10 which gives us 240 which is a factor of 2 above what has been specified as the maximum permissible level.

Again we must emphasize the necessity of our settling this idea of what is the area of uncertainty. This can only be done by statistical treatment of large numbers of samples.

The British come up with a somewhat more conservative number. On the basis of their soil and air and water measurements, they have said that if the present rate of testing continues, Britain will have 200 millicuries of strontium 90 per kilometer squared, which is roughly

500 millicuries per square mile, which is 900 micromicrocuries per gram of calcium in the soil. If we assume a discrimination factor of 10 which I like better than Dr. Neuman's factor of 8—but I think you will agree the difference is not great—then this would mean according to the British figures the average in the population of Britain would reach 90 micromicrocuries per gram of calcium indefinitely or in about 100 years of testing which is almost our maximum level of 100.

Now if we multiply that by 3 in order to allow for nonhomogenity of distribution, we have a segment of population that could conceivably go as high as 270. Then immediately we get to the most critical point, and that is: What does this mean in terms of risk to the population of the United States and to the population of the world? This is a subject about which I feel very keenly, but I know that the committee has lined up the finest experts in the country on this subject, so I think probably this is a good place for me to stop unless you want to drag it out of me by questions.

Senator ANDERSON. No; I only want to know if I understand this at the end. Is that comparable to the 100 safe figure that was being used?

Dr. LANGHAM. We have 2 bases. We have Dr. Libby's factor of 8, which gives us a level of about 24 micromicrocuries at equilibrium if we continue testing. That is on the average. So we can multiply it by 3, assuming that there is a factor of 3 spread. That would give us 72. This would then mean that there was a finite probability that a few people might go this high when the average is 24. Our maximum permissible level for larger areas of population is 100 micromicrocuries. So we can see if we continue testing weapons at our present rate, or rather injecting fission products into the biosphere at the present rate, then we would level off at about one-fourth of the maximum permissible level on the average.

There is a possibility that some people would be almost there.

If we take the British values based on soil deposition in Britain and use their factor—instead of saying 8, they really say we will reach equilibrium between 12 and 14 times, and there is a disagreement between the British and Dr. Libby—then what corresponds to the 24 in the United States goes up to 90 in Britain. What corresponds to the 72 in the United States goes up to 270 in Britain.

Senator ANDERSON. Is that 270 to be compared with the 100 which is the safe level?

Dr. LANGHAM. Yes. This is to say that the average on the basis of the value of 90 would be below the safe level if you want to call 100 safe.

Senator ANDERSON. But those people who are above the average would be right at the level.

Dr. LANGHAM. And these people with 270 would be a factor of almost 2 above this level.

Representative HOLIFIELD. Almost 3.

Dr. LANGHAM. Yes.

Senator ANDERSON. How many years would it take to achieve that?

Dr. LANGHAM. According to the British it would be reached in 100 years and according to Dr. Libby in about 50. Which of these levels you may select depends entirely on the crucial biological point, which is, is it leukemic and bone sarcoma response to radiation dose linear with dose, or is it a threshold? If it is a threshold, we have to

look at this (100 micromicrocuries) as the maximum permissible level. If it is a nonthreshold response we may look at this as an average level and try to decide what the risk is averaged over the entire population or averaged over any segment of the population.

What a nonthreshold response essentially says is that for every increment increase in dose there is an equal increment increase in effect and theoretically there is no maximum permissible level. There is an extremely small probability that any amount of radiation, the amount we wear on our wristwatches or the amount that we get from our natural potassium is going to harm somebody.

So the whole point of which of these numbers we can accept will depend upon our making a value judgment how much is atomic energy worth in cases of leukemia and bone cancer on a probability basis, averaged over the entire population or a certain segment thereof.

Senator ANDERSON. Thank you very much. I can say from personal acquaintance I know how long and hard you have worked in this field and I am very grateful to you for your testimony.

The next witness is Dr. Anderson.

Dr. ANDERSON. Mr. Chairman, I have nothing to add to the formal statement Dr. Langham made. I was in attendance only to answer questions.

Senator ANDERSON. Before we proceed with a discussion period with our several witnesses, there are several things that I would like to insert in the record at this point. First a statement by Wright H. Langham and Ernest C. Anderson. Next an article from Science Magazine, by Ernest C. Anderson, Robert L. Schuch, William R. Fisher, and Wright Langham, and finally a statement by L. D. Marinelli and J. E. Rose of the Argonne National Laboratory.

(The material referred to follows:)

SR-90 AND CS-137 IN RELATION TO THE PROBLEM OF WORLDWIDE RADIOACTIVE FALLOUT

By Wright H. Langham and Ernest C. Anderson, Los Alamos Scientific Laboratory, University of California, Los Alamos, N. Mex.

Although a number of isotopes are present in the fission mixture, the fallout of Sr-90 from weapons testing programs is the principal concern. Sr-90 is the most important isotope because of its similarity to calcium, long physical and biological half-time and high relative fission yield. These factors lead to high incorporation in the biosphere and a long residence time in bone. General contamination will result in the bones eventually reaching an equilibrium state with the Sr-90 in the biosphere.

Accepting Libby's postulation of three types of fallout (local, tropospheric, and stratospheric), levels as of the fall of 1956 were about 25 mc./mi.^{2} for the upper midwestern and northeastern sections of the United States, 16 mc./mi.^{2} for the section between 50° N. and 10° S. latitude, and about 4 mc./mi.^{2} for the rest of the world. These general values are variable, depending upon local rainfall and other meteorological patterns.

The observed levels of Sr-90 in bones of various ages are in good agreement with those calculated on the basis of a simple model of skeletal growth, remodeling and exchange. Using the data of Kulp for adults and children normalized to this model, an average equilibrium value of 3 μc. Sr-90/g. Ca is calculated for about 1975. Estimation of the equilibrium value from ecological discrimination factors suggests approximately the same average level. The normal spread of values for stable strontium and Sr-90 in human bones and for Cs-137 in people suggests that there is a very low probability that many people will show levels more than three times the average. On the basis of an equilibrium concentration of 3 μc. Sr-90/g. Ca resulting from detonations to date, about 18,000 megatons of fission could be injected at once into the biosphere before the average value would equal the maximum permissible level of 1,000 μc./g. Ca (the MPL for

industrial workers), and 1,800 megatons could be injected before reaching an average of 100 μc./g. Ca (the MPL for large areas of the population).

The above approach to the problem suggests (assuming no more weapons tests) that the average equilibrium level from weapons already tested may be about 3 percent of the MPL for the general population with a spread of from 1 to 9 percent. In terms of lifetime bone dose, these values are from 1/400 to 1/2,800 of the minimum dose from Ra 226, which has produced nonpathological bone changes. The biological significance of present and future predicted levels and whether average values may be applied to the general population depends on whether such chronic responses as bone sarcoma, leukemia, etc., to Sr–90 deposition are threshold or nonthreshold phenomena.

Estimates as to the number of megatons of fission that may be injected into the biosphere before Sr–90 becomes a serious health hazard to the general population vary by a factor of about 200. It is this variation in opinion that is responsible for much of the public confusion. Two factors that contribute a major portion of this wide uncertainty are:

1. The heterogeneity as to distribution of Sr–90 uptake in the skeleton as a function of diet and geographic location; and
2. Lack of information as to actual leukemogenic and tumorogenic response of man as a function of radiation dose.

Increased research effort to narrow the uncertainties in these two factors would seem to be desirable.

Measurements of present levels of Cs–137 in people indicate that it is of little significance in the potential hazard of radioactive fallout from weapons testing programs. Because of the chemical similarity of cesium and potassium, it is convenient to report cesium levels as Cs/K ratios. Potassium is an essential body constitutent and is itself naturally radioactive. The normal body potassium contribute 20 mr/year of the total natural yearly radiation dose of 100 mr. The present average Cs–137/K–40 total disintegration ratio is about 0.05. Taking into consideration their respective energies, the radiation dose from present levels of Cs–137 is only one-twentieth of that from natural K–40, or about 1 mr/year. This is about 1 percent of the average total natural radiation dose. The amount of Cs–137 now present in the population of the United States averages 0.006 μc., which is less than one-thousandth of the value given in the Recommendations of the International Commission for Radiological Protection as the maximum permissible level for the general population.

The short biological half-time of Cs–137 and its unavailability from soils will ensure that the levels in people will not continue to rise in the manner of Sr–90. The cesium levels will follow the rate of fallout and not integrated total accumulation.

Since Cs–137 does not show unusual concentration in the gonads, present levels in people will contribute only about 1 mr./year, or about 1 percent of the natural background level, to the genetic radiation dose.

The study of the distribution of Cs–137 should be continued to furnish information on fallout phenomena and to provide a measure of the rate of fallout and the amount of stratospheric storage, since this information might make considerable contribution to the solution of the Sr–90 problem.

[Reprinted from Science magazine, June 28, 1957]

Radioactivity of People and Foods

Ernest C. Anderson, Robert L. Schuch, William R. Fisher, Wright Langham[1]

The problems of widespread, low-level radioactive contamination from nuclear weapons testing have been increasingly before the public during the past year. The principal concern is the fallout and entry into the biosphere of strontium 90. There is general agreement that present levels of strontium 90 in foodstuffs and in the human body are far below the most conservative permissible amounts; however, the human burden of strontium 90 may be expected to rise as a result of deposition of stratospheric debris from weapons already (and subsequently to be) tested. Predictions based on conservative assumptions indicate that there remains a considerable margin of safety. If the rate

[1] Dr. Anderson, Mr. Schuch, and Dr. Langham are members of the biomedical research group at Los Alamos Scientific Laboratory, University of California, Los Alamos, N. Mex. Mr. Fisher, a former member of the group, is now at the University of Colorado School of Medicine, Denver.

of weapons testing continues to increase, however, this margin may eventually disappear.

Although the permissible levels contain inherent safety factors, it is essential that close attention be devoted to all aspects of the fallout problem during the next several years. Only in this way can advance notice of the possible approach to permissible levels be obtained and assurance given that they will not be exceeded inadvertently. Recent reports of the National Academy of Sciences-National Research Council Committee on the Biological Effects of Atomic Radiation (1) support the importance of systematic measurements of general levels of radioactivity in order that information on the rate of accumulation of extraneous radioactivities may be obtained while the latter are still below natural levels.

Large-scale production of nuclear power will create problems of a similar nature. A 100-megawatt (heat) reactor will, in one year of operation, produce the same quantity of long-lived fission products as the detonation of a 1-megaton fission bomb. The estimate of the United States nuclear power production rate by 1975 is 20,000 to 40,000 megawatts, and the United Kingdom expects to be producing 6,000 megawatts by 1965. Reactor-produced fission products constitute a much less immediate problem than those from a bomb test, since more control can be exercised over their immediate fate, but disposal of the fission products must eventually be made.

If disposal is to be simple enough to make nuclear power economically competitive, dispersal by natural means such as ocean burial or other means may have to be resorted to. This will increase the possibility that reactor-produced fission products may ultimately enter the food cycle and reach man. The basic problems of permissible body burdens and distribution mechanisms in the biosphere, therefore, are similar for bomb and reactor debris, and information gathered in the study of the former problems should prove valuable in the latter.

An extensive survey of strontium 90 levels (Project Sunshine) has been underway for several years, and the results have been reported by Libby (2–4) and by Kulp (5). Because strontium 90 and is daughter yttrium 90 emit only beta rays, analysis requires time-consuming and destructive chemical separations. Detailed studies of the temporal and spatial distribution of long-range fallout would be easier if they could be based on a gamma-emitting nuclide. The discovery of the presence of the fission product cesium 137 in human beings and in foodstuffs by Miller and Marinelli (6) provides a possibility of such an approach.

Similarity of the decay chains of the fission products of mass 90 and mass 137 indicates that distribution of cesium 137 and strontium 90 in bomb debris will be similar:

$$\text{Kr–90} \xrightarrow{\text{33 sec}} \text{Rb–90} \xrightarrow{\text{2.7 min}}$$

$$\text{Sr–90} \xrightarrow{\text{28 yr}} \text{Y–90} \xrightarrow{\text{64 hr}} \text{Zr–90 (stable)}$$

$$\text{I–137} \xrightarrow{\text{19 sec}} \text{Xe–137} \xrightarrow{\text{3.4 min}} \text{Cs–137} \xrightarrow{\text{27 yr}}$$

$$\text{Ba–137m} \xrightarrow{\text{2.6 min}} \text{Ba–137 (stable)}$$

Both nuclides have two gaseous or volatile predecessors with appreciable half-lives. Strontium 90 and cesium 137 are formed at relatively late times after bomb detonation and are not proportionally included in the larger and more refractory particles which fall out locally. Stratospheric storage and distant deposition will be high for both nuclides, and their ratio in distant fallout should be approximately that calculated from the known fission yields. Once strontium 90 enters the biosphere, its behavior becomes very complex. Its concentrations along the ecologic chain change slowly and reflect a summation of all past fallout. In addition, it enters plants both through the soil (in some relationship with available calcium) and by foliate absorption from direct fallout.

One very important and difficult problem is to determine the fraction of strontium 90 entering the ecologic chain by way of these routes. Cecium 137, however, is apparently poorly taken up from the soil by plants (7) and its biological half-times (8) are comparatively short (140 days in man (9) and 20 days in the cow (10)). These factors suggest that cesium in people and in milk and other foodstuffs may be a direct and relatively simple measure of fallout rate. One should be able, therefore, to make a direct determination of fallout rate as a

function of geographic location and time, as well as of changes in stratospheric storage following test operations, by measuring cesium 137 in biological materials. Cesium 137 measurements on soils might provide a more convenient method than strontium 90 measurements for estimating integrated fallout.

Cesium 137 and strontium 90 also are similar in that they are soluble and closely related to potassium and calcium, respectively, which are normal base exchange cations in soil and essential constituents of living matter. In this they differ from other high-yield fission products such as zirconium-niobium 95, ruthenium-rhodium 106, and cerium 144, which have been observed in rug dirt by Miller and Marinelli at Argonne National Laboratory (11) but which are apparently not ecologically concentrated and have not been detected in the general population and in foodstuffs.

POTASSIUM 40 AND CESIUM 137 IN PEOPLE AND FOODSTUFFS

After the announcement by Miller and Marinelli of the presence of cesium 137 in people (6), an intensive program of study of this nuclide in people and in foodstuffs was begun at the Los Alamos Scientific Laboratory. Some 1,500 measurements were made; preliminary results have been reported previously (12). This article (13) summarizes the data collected during 1956. A compilation of all the primary data is being prepared as an unclassified laboratory report which will include detailed analyses of procedures, sources of error, and other information.

Measurements were made with the Los Alamos "human counter" (14), a large liquid scintillation detector that is capable of counting gamma rays from human subjects and from samples of foodstuffs up to several hundred pounds in weight with 100 percent geometrical efficiency. Although the energy resolution of this detector is quite limited compared with that of a sodium iodide (thallium) crystal, it is adequate to permit the simultaneous determination of the cesium 137 (0.661 Mev.) and potassium 40 (1.46 Mev.) gamma rays. Its ultimate sensitivity is 0.0005 microcurie of gramma activity (20 disintegrations per second) for only 100 seconds of counting time. If a 100-kilogram sample is counted, this corresponds to a specific activity of 5 times 10^{-15} curies per gram, which is far below the natural radioactivity of most materials. The natural potassium 40 radioactivity of man (about 0.013 microcurie as gamma rays) can be measured to a precision of better than 5 percent in less than 2 minutes. The cesium 137 determination has a precision of 0.001 microcurie for the same counting time.

Potassium 40 in people.—The average potassium content of the adult male is estimated to be about 133 grams (6, 15, 16) (0.19 percent of gross body

weight of the standard man), which is equivalent to about 400 potassium 40 gamma disintegrations per second.

Figure 1 gives the natural potassium 40 gamma activity of 164 representative subjects, 81 of which were reported earlier (17), plotted against gross body weight. These data show a pronounced scatter of the points to the right of a limiting line and a definite difference between males and females. Correlation of potassium 40 activity with the fat-free body weight of a select group of these subjects indicated the amount of fat to be the principal factor causing variation in apparent potassium content of the body (17). The total body potassium expressed as percentage of gross body weight will show considerable variation, therefore, depending on sex, age, weight, body type and physical activity, but it can be accurately calculated from a determination of total body water.

In figure 2 the specific activity of potassium 40 (gamma disintegrations per second and pound) is plotted against subject age. These data confirm the general decrease of potassium with age reported by Sievert (16). The solid lines indicate the probable upper limits for uncontaminated male and female subjects, respectively. Not enough children have been measured for us to be certain of the trend below age 15. The dashed lines, therefore, are estimates over this region. Deviation from these curves is an indication of possible surface contamination of individuals during periods of local fallout, since only 0.002 microcurie of hard gamma contamination is sufficient to raise the average adult from the lower to the upper limit of the specific activity distribution.

Cesium 137 in people.—Libby (2) adopted the procedure of reporting strontium 90 results as strontium 90/calcium ratios because of the metabolic similarity of strontium and calcium and to facilitate the comparison of different types of materials. Our cesium 137 results are reported as cesium 137/potassium 40 ratios for similar reasons. The principal differences in the biological behavior of the two elements can be accounted for in terms of the appropriate biological half-times. The ratios are reported as the ratio of cesium 137/potassium 40 gamma disintegrations (18).

Figure 3 summarizes the measurements of cesium 137/potassium 40 ratios in people for 1956. The triangles represent results in people from various parts of the United States (the distribution is indicated on the map, fig. 4). Each point is an average for 10 to 20 persons, and the range of values before averaging was 0.1 to 0.9. The circles are averages of measurements on a local control group of 10 laboratory personnel. The scattered high values during the period from June to September are probably the result of surface contamination from tropospheric fallout during Operation Redwing. That they were caused by surface contamination was indicated by their sudden rise and fall, by abnormally high apparent potassium 40 values during the same period, and by the fact that these high apparent potassium 40 values were reduced to normal after bathing in those cases in which remeasurement was possible.

Because of this evidence of external contamination, a line through the more reproducible lower limit of the distribution is regarded as representing the trend of internal activity. The data from the two groups agree in that they indicate a slight rise during the spring followed by a slow decline during the fall. The control group was apparently somewhat lower in the spring, but in the fall the two groups were indistinguishable.

General 1956 averages of cesium 137/potassium 40 ratios for people from various States are presented in figure 4. The results are surprisingly uniform in view of the sizable variations among individuals from the same State. Uncertainty in the averages due to small sample size precludes any deduction of fine structure until more data are available. Within the range 0.5 ± 0.2, the cesium 137/potassium 40 ratio is essentially uniform over the United States, except during periods of tropospheric fallout.

The frequency distribution of potassium 40 and cesium 137 in the population sample is essentially normal. The potassium 40 frequency curve is given in figure 5 as a histogram with a normal error curve fitted to it. The standard deviation of the normal curve is 18 percent. The subsidiary peak outside the normal curve is caused by surface contamination during periods of tropospheric fallout.

Figure 6 shows the corresponding frequency curve of the cesium 137 data for the same population sample. Distribution is again normal, but the width is twice as great as that of potassium 40, the standard deviation being 36 percent. The smaller deviation of the potassium 40 data probably reflects control of the potassium 40 level of the body by a homeostatic mechanism that is not highly de-

pendent on intake. The cesium 137 burden, however, may vary with the dietary habits of the subject and the concentration of cesium 137 in his foodstuffs.

Libby (19) has shown that other trace elements, such as stable strontium, strontium 90 and radium 226, show normal frequency distribution curves with deviations comparable to that observed for cesium 137.

The abnormal subsidiary peak shown in the potassium 40 distribution curve is not present in the cesium data. This indicates merely that the surface contamination distorting the potassium 40 level was present in the cesium 137 channel to a proportional extent and left the cesium/potassium ratio unaffected.

Cesium 137 in milk and other foodstuffs.—Figure 7 summarizes the measurements of cesium 137/potassium 40 ratios in milk during 1956. A peak in cesium 137 activity during July, presumably woing to tropospheric fallout from Operation Redwing, is clearly visible in Wisconsin and New Mexico samples, but is absent from Kentucky milk. This observation is consistent with the path of the cloud as estimated in the United States Public Health Service air sampling network. A peak in the activity in Wisconsin milk in October is indicated also; it may be the result of a foreign test.

Data on geographic distribution of the cesium 137/potassium 40 ratio in milk are as yet scanty, but are summarized in figure 8. As with the measurements of people, one concludes that distribution is essentially uniform within the limits of the data. The uniformity, of course, applies only to the periods in which tropospheric clouds are not present. It is interesting that the two Australian milk samples (fig. 7) are in agreement with the general United States average, lending support to the assumption that the general levels are derived from the stratospheric reservoir. A sample of American dry milk produced in 1942 showed no detectable cesium 137, the cesium 137/potassium 40 ratio being less than 0.02.

Some preliminary measurements of cesium 137 in foodstuffs other than milk are given in table 1. During the spring of 1956, beef and lamb showed a ratio comparable to that of people but considerably higher than similar samples collected in the winter of 1956–57. During both periods, beef and lamb consistently ran higher than pork, which might be expected from the differences in grazing and feeding habits. One sample of dried blood collected in April 1952 showed a ratio less than one-third that of samples collected during the winter of 1956–57.

DISCUSSION

Measurements of present levels of cesium 137 in people indicate that it is of little significance in the potential hazard of radioactive fallout from weapons testing programs. The present average cesium 137/potassium 40 total distintegration ratio is about 0.05. Taking into consideration their respective energies, the radiation dose from present levels of cesium 137 is only one-twentieth of that from natural potassium 40, or about 1 milliroentgen per year. This is about 1 percent of the average total natural radiation dose and less than 10^{-3} of the dose of cesium 137 given in the recommendations of the International Commission for Radiological Protection as the maximum permissible level for the general population (20). Interest in cesium 137, therefore, centers on its potential usefulness in the study of fallout mechanisms.

A rough quantitative comparison of the present average strontium 90 and cesium 137 levels in people is of interest. According to Libby (3), the strontium 90 level in children is about 0.001 microcurie. A fractionation factor of about 10 against strontium between primary fallout and human bone is indicated by the stable strontium data (21) (that is to say, the strontium/calcium ratio in soil is 10 times the strontium/calcium ratio in bone), but cesium can be assumed to be quantitatively absorbed by both cow and man. Although strontium will continue to accumulate because of its long biological half-time, the effective accumulation time for cesium will be limited to some 200 days. If stratospheric fallout is assumed to have begun with Operation Castle (1954), strontium 90 has been accumulating for some 2 years, and this factor will cause it to exceed cesium 137 by $2\times365/200$, or 3.6. Finally, the relative activity yield in the fission process is 1.27 in favor of cesium (assuming fission yields of 0.0510 and 0.0620 for the mass 90 and mass 137 chains and half lives of 27.7 years for strontium 90 and 26.6 years for cesium 137). The overall factor is then $10\times1.27/3.6$, or about 3 for cesium 137, and the estimated level based on a strontium level of 0.001 microcurie is 0.003 microcurie. Considering the crudity of the several approximations, this is in surprisingly good agreement with the observed average of 0.005 microcurie.
